A SERIES OF ONE THOUSAND CASES OF ABDOMINAL SECTION.

By LAWSON TAIT, F.R.C.S.,

BIRMINGHAM, ENG.

THE conclusion of such a series affords a suitable time for a retrospect and a critical examination of the results of the work and a consideration of what general conclusions may be drawn from them.

The first point for consideration is an accurate determination of the meaning and application of the term abdominal section, and this is by no means so easy a matter as might at first sight be imagined. I have gathered from the writings of others that there is by no means a complete agreement on this point, and there are several of my own cases upon whose classification I have considerable doubt. The commonly accepted view is that an operation is not an abdominal section when the peritoneum is not opened, yet there are many operations where this is done that are not, at least so far have not, been classified as abdominal sections. Thus herniotomy, when the sac is opened, would be an abdominal section if this definition were logically followed. The removal of a kidney or the opening of the colon might or might not be an abdominal section by the accidental peculiarities of any particular case. Indeed, numerous difficulties may be raised. Any definition can be objected to, and no hard and fast line can be logically followed, but it seems to me that less confusion will arise upon the discussion of many points if we take the definition I have indicated, and therefore I follow it. The only changes effected by it upon the series already published are that a few kidney operations, all successful, are excluded, as are also two cases of removal of extraperitoneal cyst, both fatal operations. The difficulty mentioned in connection with herniotomy does not occur in my practice, as I do not perform such operations save in the umbilical variety, and that operation no one can object to being classed as an abdominal section.

I desire it to be understood, therefore, that in all of the cases in the following analysis of the series, the peritoneum has been involved.

ANALYSIS.

	Cases.	Deaths.	Percentage. Mortality.	
Exploratory incisions	54	2	2.1	
Cystoma—Parovarian	65	2	3.07	8.1
Cystoma—One ovary	239	26	11	8.1
Cystoma—Both ovaries	101	5	5	8.1
Removal of appendages for myoma	99	7	7	
" " " " inflammatory disease	201	10	5	
" " " " epilepsy	6	0	0	
" " " " deformity	1	0	0	
Hysterectomy	54	19	35.7	
Opening for draining pelvic abscesses	30	0	0	
" " incomplete operations	30	15	50	
" " cholecystotomy	13	0	0	
" " nephrectomy	3	0	0	
" " nephrotomy	9	0	0	
Extra-uterine pregnancy	11	2	18	
Hepatotomy for abscess and hydatids	10	0	0	
" " hydatids of peritoneum	2	0	0	
Tumors of omentum and mesentery	5	0	0	
Enterotomy	8	1	12.5	
Adhesion of intestines relieved	2	0	0	
Chronic peritonitis opened and drained	7	1	14.3	
Acute peritonitis	2	1	50	
Umbilical hernia	4	0	0	
Cæsarean section	1	1	100	
Scirrhous tumor of abdominal wall	1	0	0	
Suprapubic lithotomy	1	0	0	
Enucleation of myoma	1	1	100	
	1,000	93		

The question of the best anæsthetic for use in abdominal surgery is one to which of course I have given a very large amount of attention, and it is very singular that in the class of drugs, the action of which there can be the least doubt about, we are as yet certainly very unsettled in our views. Like all pupils of Simpson, I began my professional life with a most profound belief in the advantages of chloroform over all other anæsthetics. I have never seen an accident from chloroform, but partly by reason of the fear of inquests and partly by the example and teaching of Dr. Keith, a belief grew in my mind that ether was preferable to chloroform, and at first I had the impression that the sickness after ether was less marked than after the use of its rivals. I was not, however, very long in discovering that ether has special risks for people with a tendency to bronchitis; and later on I discovered, and have already published the fact that during the administration of ether the secretion of urine is completely arrested. It was subsequently very forcibly impressed on me that for patients with damaged kidneys ether is a dangerous anæsthetic, and although I cannot say that I have seen any fatal results arising from this peculiarity of its action, I certainly have had abundant cause to fear it. My first alteration, therefore, in my views concerning ether was to limit its application to patients under forty, but even after this I found my confidence in its safety greatly diminished by the fatal occurrence of bronchitis in a case of hysterectomy in a woman aged thirty. In this case the patient's breathing was embarrassed from the moment she recovered from the anæsthetic, her urine was scanty and became ultimately albuminous, and she died on the fourth day from suffocative catarrh, the post-mortem showing that so far as the operation was concerned everything was perfectly satisfactory.

Among my other experiences of anæsthetics was the employment of bichloride of methylene and of Richardson's mixture, generally known as methylene ether. The latter is by far the most easy of employment of all the anæsthetics I have seen tried. Patients recover more rapidly from it and seem to be less affected by it than any other anæsthetic; but I had a death from it, and on that account promptly gave up its use. The bichloride of methylene has many advantages, but it has one practical disadvantage, that its application requires a special apparatus and an amount of skill in the employment of that which cannot always be had. I have also found that the sickness after it is more persistent and troublesome than after ether or chloroform, and there are some patients who are kept under its influence with very great difficulty. A further objection to it is that it does not keep well, and it certainly is not commonly supplied in a pure condition, so that my employment of it was not very extensive. The last stage of my experience in the employment of anæsthetics is the use of a mixture of two parts of ether and one part of chloroform, given by means of Clover's apparatus. This mixture is rapid in its action, is not at all unpleasant to the patient, and certainly the sickness after it is far less than with anything else I have ever used. I cannot say that I think it more safe than any other anæsthetic, for we may be quite certain that with none of these drugs will there ever be absolute security against accidents, but I have seen no bronchitis after its use; it has no effect in arresting the secretion of urine, and, on the whole, I am far better pleased with it than any other, and I may say that

Dr. Annie Clarke, who has now been my administrator through a very extensive experience, is quite in agreement with this conclusion.

The first point to attract attention is the general death-rate, 9.3 per cent. Whether this is high or low I cannot say, for no such series has before been published, and, therefore, I cannot discuss it relatively. I think it high, and am perfectly certain that if I live to complete another such series it will have a very much lower mortality, and for two reasons: In the first place, the present series contains my early work, where the want of experience told heavily. Contrasting the results in my first series of fifty ovariotomies (thirty-eight per cent. mortality) with my last three hundred and thirteen (4.76 per cent. mortality), is enough of itself to indicate the terrible influence of want of experience; and though other factors enter into the explanation of this great difference, the influence of inexperience is everywhere visible. In hysterectomy it is very evident, and in the removal of diseased appendages, but it is most apparent in the undue preponderance of incomplete operations in my early practice. Many operations were then left unfinished which would not be so now, and thereby a heavy item of mortality would be removed.

This quite justifies what I said in my first contribution to abdominal surgery, that in this branch of our art "more, I think, than in any other in the whole field of surgery, does the personal experience of the operator, gained by failures and hair-breadth escapes, serve him in good stead for his subsequent work."

The second reason from which I predict that my second series of a thousand cases will have a much lower death-rate is that important causes of failure have been completely removed by the discontinuance of the clamp in ovariotomy and of the ligature in hysterectomy, and cases of all kinds are now operated upon at earlier stages of these diseases than they were when I first began my work, all of which points will be discussed in their proper places.

The first group of cases of which I have to speak is formed of ninety-four exploratory incisions, made for the purpose of ascertaining exactly the state of matters inside the abdomen and settling any doubt as to the diagnosis and prognosis in each case. Ninety-four is a large number, but it must be remembered that years ago I advocated an exploratory incision in preference to a first tapping, and that I have persistently carried out the practice. As I have said many times before, so I say again now, I make exploratory incisions to be sure that I am not wrong, whereas formerly I used to make them only to find I was entirely mistaken. They serve the purpose of complete tappings, and, as the patients almost uniformly recover, they do no harm at all. There are two deaths recorded in this group, but I might have eliminated these two cases with perfect fairness, for one died really of the prolonged sickness after the anæsthetic, a broken-down old woman of sixty, and in the other I passed a trocar into the irremovable tumor, so that the operation was not strictly limited to mere exploration.

In nearly fifty of the cases the exploration has amounted merely to a tapping. Occasionally it was followed by drainage, and in some of these cases results of the most marvellous kind have followed—results which have completely justified the practice. In four cases I have explored the abdomen to see if I could remove the spleen, and in two of these the enlargement of the organ has completely disappeared, and the patients have now perfect health. In one case, resident in London, I opened the abdomen and found a large tumor of the liver, which seemed to me to be certainly malignant. The ascitic effusion has not occurred again, and the tumor now, nearly a year after the operation, is certainly less than half of its original size, and the patient is rapidly getting well. In five cases, where there was a large effusion due to papilloma, mere exploration has completely cured the patients, a singular fact that I have already drawn attention to. It is perfectly impossible to understand this, just as it is perfectly impossible to understand how papilloma in two cases, presenting in every detail identically the same characters, is a curable disease in one and a rapidly malignant disease in the other. But of this there can be no doubt now, for my original observation has been fully confirmed by Mr. Albon Doran. Several cases have also been published where pelvic pain has been relieved in a most inexplicable way by mere exploration.

The great advantage, however, of this extended application of abdominal section is most apparent in other groups where tumors have been removed and diseases cured under circumstances apparently hopeless, and when the operation was begun under the belief that nothing satisfactory could be accomplished.

The next group includes four hundred and five cases of cystomata. Of these I have nothing new to say; there is nothing that I have said of recent years that I have to unsay, unless it be that I have an impression that in some previous paper I have said that I never lost a case of removal of a parovarian cyst. I cannot find the statement, but I have a strong impression that I did say it, and now I display a group of sixty-five cases of removal of parovarian cysts, with two deaths. These two cases have been dissected out of my earlier lists published before I recognized the importance of separating parovarian from ovarian cystomata. The explanation of the fatalities is that they were clamp cases.

Upon the subject of the clamp, as on the subject of Listerism, I have nothing more to add to what I have already said, and the following analysis of the four hundred and five cases proves, as clearly as any figures can indicate a conclusion, that the clamp was the chief cause of my early mortality, and that Listerism had little or no influence one way or the other.

	Cases.	Deaths.	Mortality, per cent.
Clamp (Listerian)	36	9	25
Clamp (non-Listerian)	26	7	27
Ligature (Listerian)	30	2	6.6
Ligature (non-Listerian)	313	15	4.80
Total	405	33	8.15
Extraperitoneal cases	62	16	25.7
Intraperitoneal cases	343	17	4.58

The diminution of mortality, about two per cent. in the group of cases (313) where I used the intraperitoneal method without Listerian details, when compared with the group (30) when I used the same method with Listerism is in all probability due to increased personal experience. I have only further to say that as far as I am concerned this statement ends all discussion of this much-debated subject, unless something should happen to alter my opinions about it. For the present I am tired of wrangling about it.

The third group contains ninety-nine cases of removal of the appendages for the arrest of the growth of uterine myoma and for the hemorrhage due to that disease; and in connection with these cases it will be convenient to discuss the group of hysterectomies, fifty-four in number

Nothing could be more startling than the different mortalities of these two operations, and it is only fair to the first of the two to say that five out of the seven deaths occurred in the early part of my practice, and that the other two might very fairly be reckoned on a list of what Mr. Bryant calls "too late" cases. My belief is now firmly established that if this operation were performed as soon as symptoms drew attention to the disease its mortality would be hardly appreciable, and it would restrict the necessity of the terrible operation of hysterectomy to a very small group of cases. I am glad to know that in this view I am supported by Mr. Knowsley Thornton. The operation is very often not an easy one, and in the earlier part of my practice it happened three times that I was unable to complete the operation; one of these cases died. In another I could neither remove the appendages nor the tumor; it went on growing, and was removed (hysterectomy) some years after

by Mr. Knowsley Thornton, with a fatal result. The third incomplete case died, I am informed, about two years after my attempt, from protacted hemorrhage.

The ultimate results of about a third of these cases I have already published, and the whole of them will form the subject of a detailed paper when a sufficient time has elapsed to enable me to obtain fair conclusions.

DRAINAGE-TUBES ACCIDENTALLY LOST IN THE PLEURAL CAVITY IN CASES OF EMPYEMA.[1]

By F. HUBER, M.D.,

CLINICAL ASSISTANT, DISEASES OF CHILDREN, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Case I.—Willie O——, a flabby, fat, rachitical boy, has been under my care at various times. At the age of nine months was treated for an extensive erysipelas of lower extremity, back, and abdomen. Later on had measles and several attacks of intestinal catarrh. December 6, 1881 (when nineteen months old), was suddenly taken with fever, cough, and pneumonic breathing. During the following weeks he became very much emaciated, had diarrhœa, fever (high at outset, became moderate later on). As flatness over left side of chest did not diminish, and as the diarrhœa persisted, though the fever was not very high, a purulent effusion was suspected. Diagnosis verified by the hypodermic syringe.

December 30th.—Withdrew about half-pint of pus by means of a Dieulafoy's aspirator. Further attempts at removal of fluid, as also the antiseptic washing-out of abscess cavity, had to be abandoned, as large pieces of lymph occluded the needle of aspirator.

December 31st.—Assisted by Drs. F. A. Beck and J. F. Golding the child was put under chloroform and a free opening was made in the eighth intercostal space laterally. About a quart of matter mixed with numerous large pieces of lymph escaped. A drainage-tube about nine inches long was then introduced, and the cavity was washed out with a weak solution of carbolic acid. A large pad of oakum and a bandage completed the dressing. The child was then put to bed and placed upon the left side, so as to allow of free drainage. Under the daily use of carbolated injections the cavity gradually diminished in size, and at the end of about a month the drainage-tube was permanently removed; two weeks later the external wound also healed.

In this case I made use of a long drainage-tube. The first four inches only were perforated with lateral openings. At the time of making the injections the tube was introduced nearly its entire length, so that deeper portions of cavity would be thoroughly washed. Then the tube would be withdrawn up to fenestrated portion, and the non-fenestrated external extremity was secured to chest-wall by a broad strip of adhesive plaster; a large pad of oakum was placed over the wound and tube, and a bandage tightly applied around the chest. One day, upon removing the dressing, I found the plaster loosened by the discharge and the tube had disappeared. The lips of the wound were then separated by dressing-forceps and the tube indistinctly seen at the bottom was readily seized and removed by means of a pair of forceps.

The tube was then secured by means of a silk thread passed through rubber about one-fourth inch from its outer end—the other end of silk being fastened to bandage with a safety-pin. The accident in this case was fortunately remedied in a simple manner. Presented at Dr. Jacobi's clinic in latter part of February, 1882, the lung was found fully expanded; breathing and voice heard all over left lung. No subsequent retraction of chest-walls.

Case II.—Jennie D——, twenty-seven months old, seen October 29, 1883. The child had been taken sick two days before with a slight cough, fever, and pain in right side of thorax when lifted up. A scarlatinal eruption existed upon the back and extremities—very restless. Temperature 104° (rectal).

September 3d.—Eruption disappeared. Full developed pleuro-pneumonia of right side. No subsequent desquamation; diarrhœa.

September 15th.—As flatness did not diminish, temperature continued elevated, and diarrhœa persisted, a hypodermic needle was introduced and pus withdrawn.

September 16th.—Chest aspirated and about a pint of pus removed. The needle being now occluded, further withdrawal of pus and antiseptic washing had to be given up.

September 21st.—Incision made in eighth intercostal space laterally, and over a quart of foul-smelling pus mixed with numerous pieces of lymph escaped. Drainage-tube introduced and cavity washed out with weak solution of carbolic acid. Not desirous of a repetition of the accidental entrance of the tube into the chest, I considered myself secure by taking the precaution to transfix one end of tube with a safety-pin. A large pad of oakum and a bandage completed the dressing. Child then placed in bed upon the affected side. Temperature 104½°, next morning 100°.

September 24th.—Upon removing the dressing, mother found the closed safety-pin upon the oakum. Diligent search failed to discover tube.

September 26th.—Numerous foul, decomposed pieces of lymph were washed out. From this time on temperature did not exceed 101°. No septic signs until October 5th. Temperature rose to 102°, and orifice closed. Upon dilating opening with Trousseau's tracheal dilator, about two ounces of pus escaped. No smell. Slight diarrhœa.

October 6th.—Temperature is normal in morning, 104½° in evening. Quantity of pus increased and foul.

October 7th.—Temperature 100°. About three ounces of pus evacuated. No smell.

October 8th.—Temperature 103° at 8 A.M. Pus fetid; wound again dilated and cavity hyperdistended with a weak solution of carbolic acid; about half an ounce of blood discharged. 9 P.M.—Temperature, 100°; discharge grumous.

October 9th.—Temperature, 101½° at 8 A.M., 100° at 12 M., 103° 9 P.M. Several attempts had been made to discover the whereabouts of tube in chest; forceps of different sizes and shapes were used. Septic symptoms continuing a radical operation was done October 13th, under Dr. A. Jacobi's supervision, and with his kind assistance, as also that of Drs. Golding, Breyman, and Scheersinger, a final attempt was made.

Forceps of various kinds were used by Dr. Jacobi and myself. As the opening would not admit a finger, it was decided to remove a portion of a rib. The original wound in eighth interspace was enlarged down to rib. The periosteum was then incised and peeled of so as to expose about one and a half inch of eighth rib. Bone cut by a pair of bone forceps and about an inch removed. The original wound in pleura was then enlarged by means of Trousseau's tracheal dilators. The index finger was then introduced into wound, and after a little search the tube was felt near the vertebral column. It was hooked up by finger and readily removed by forceps.

It gave off an exceedingly offensive odor, and upon closer examination we found that the rubber had been torn through by the safety-pin. A larger tube, fastened by safety-pin and silk, was then introduced. The chest was then washed out. A large pad of oakum and bandage around chest completed the dressing. Temperature at time of operation, 3 P.M., 103°; at 9 P.M., 101°.

Further progress favorable until October 25th; then temperature rose rather suddenly to 104° at 10.30 A.M., 102° at 9 P.M.

October 26th, 100½° at 10.30 A.M., 105° at 5.30 P.M.; October 27th, 99° at 8 A.M., 101° at 8 P.M.; October 28th, 98° at 8 A.M., 103¼° at 7 P.M.; October 29th, 99° at 8 A.M., 104° at 7 P.M.; October 30th, 99½° at 8 A.M.,

[1] Read before the New York Medical Union, October 14, 1884.

102¼° at 7 P.M.; October 31st, 99° at 8 A.M., 101½° at 7 P.M.; November 1st, 99° at 8 A.M., 103° at 7 P.M.; November 2d, 99° at 8 A.M., 100° at 7 P.M.; November 3d, 99° at 8 A.M., 103½° at 7 P.M.; November 4th, 99° at 8 A.M., 100¼° at 7 P.M.; November 5th, 99° at 8 A.M., 99° at 7 P.M.; November 6th, 98⅝° at 8 A.M., 99° at 7 P.M.; November 7th, 99° at 8 A.M., 100° at 7 P.M.; November 8th, 98⅝° at 8 A.M., 99½° at 7 P.M.; November 9th, 99° at 8 A.M., 101° at 7 P.M.; November 10th, 99° at 8 A.M., 99° at 7 P.M.; November 11th, 99° at 8 A.M., 99° at 7 P.M.; November 12th, 98⅜° at 8 A.M., 98⅜° at 7 P.M.; November 13th, 98⅜° at 8 A.M., 98⅜° at 7 P.M. Increase in cough, dyspnœa, and râles point to a pneumonia of right side.

November 14th.—As cavity would not hold over a few drachms, the tube was permanently removed and a plug of oakum inserted. Superficial necrosis of both ends of cut rib; two small spiculæ subsequently escaped, and toward end of November wound all healed. Later on a small abscess formed, and another piece of bone came away. Discharged cured during latter part of December. Lung fully expanded; no retraction of chest. The patient had been presented at the Children's Clinic several times, and to Dr. Jacobi my thanks are due for advice and assistance rendered during the progress of the case.[1]

The successful result in the above cases (restoration with full expansion of lung) is mainly due to the early removal of the fluid—accomplished before the lung had sustained any material damage from compression, or had been bound down by adhesions. In this connection it may be well to draw attention for a moment to the following, abstracted from an editorial in the London *Lancet*, 1880, p. 181, part 2, American reprint:

"An empyema can never be cured unless the cavity of the pleura is obliterated by the expansion of the lung, the displacement of viscera, or the falling in of the chest walls, or all of these together. But only when the lung expands to its former size have we any right to speak of a 'cure' having been accomplished; in the other cases recovery may have resulted, but the patient is sadly crippled, having a much diminished breathing power. We cannot keep this consideration too constantly and clearly in view; it is not enough to save the life in such cases, we ought also to save the lung, and it is as much a stigma on surgery to allow a patient to recover with a collapsed useless lung as to permit anchylosis of the hip to occur in a false position."

In view of the numerous excellent articles published in the journals lately, a general survey of the subject of empyema, though interesting, is beyond the scope of this paper. I shall not concern myself with the etiology, symptomatology, pathology, etc. The treatment varies widely with different authorities, and to go into details in regard to the various plans followed would lead me too far. I shall limit myself principally to the consideration of a mishap incidental to the employment of the drainage-tube—namely, the accidental loss of the tube in the thoracic cavity.

This complication is unfortunately not an infrequent occurrence. I have come across a number of cases in a not very extended research into various English, French, German, and American medical journals. The instances, however, are more numerous than we would infer from reported cases. The explanation is obvious. The accident is associated in the minds of many with extreme and even criminal carelessness, and thus many cases are not published because of the fear of adverse criticism. Hospital surgeons have met with this accident in their own practice; and it has occurred when recognized precautionary measures have been resorted to.

No longer surgical curiosities, the cases form an interesting series and merit more than a passing notice.

L. Solomonson recommends that the drainage-tube be passed through a disk of leather and fastened with wax, in order to avoid the accident ("Virchow's Jahresbericht," 1875, vol. ii., p. 195).

Berkeley Hill ties a piece of silk thread firmly to the outer end of the tube, and secures that to the skin by placing over it a good-sized disk of diachylon plaster three or four inches above the wound, to prevent the tube slipping into the cavity—a mishap that has occurred ere now (*Lancet*, July 17, 1875).

Case III.—J. Radek reports a case of a medical man, twenty years of age, with an empyema operated upon by some one else; suppuration was profuse, and death occurred in a few months in consequence of inanition. At the autopsy a tube was found floating in a quantity of pus ("Virchow's Jahresbericht," 1876).

Case IV.—E. D——, twenty-one years of age; tube slipped into chest, July, 1876, and on Christmas second tube was lost. As the surgeon in charge was unable to remove them, the patient went to St. Francis' Hospital. Operated upon January 18, 1877. Dr. Ripley made an incision in seventh intercostal space, six and one-half inches from median line, and prolonged it backward about four inches. The seventh and eighth ribs were closely approximated and necrosed where tube had been in contact. Before proper instruments could be used, a portion of eighth rib was excised. (An angular fracture of the seventh rib was found, caused probably by attempts to force ribs apart in operations performed before admission.)

The cavity was then explored with uterine forceps and Emmet's silver probe, bent at extremity to form a hook. After repeated attempts the two tubes were found posteriorly and superior to incision, about one inch apart. First tube, seven inches long; diameter, goose-quill. Second tube, six inches long (Medical Record, 1877, vol. xii., p. 150).

Case V.—H. F——, female, twenty-six years of age; admitted to Charing Cross Hospital with empyema of right side and possibly phthisical changes in same lung. Aspirated January 8th, chest opened 10th, and drainage-tube of ordinary gum-elastic catheter used. Slipped into cavity 22d, and removed 24th. The piece of catheter, two and one-half inches long, was carefully secured by tying it with thread, but owing to some unexpected movement of the patient these threads were broken. An incision was made parallel to upper border of eighth rib and a bent probe passed in. After a little manipulation the tube was felt, seized, and successfully removed (J. A. Bloxam, *Medical Times and Gazette*, vol. i., p. 149. London, 1880).

Case VI.—Dr. R. Abbe was called in consultation to see a boy, five years of age, with an empyema operated on two months before. A drainage-tube had slipped into chest a fortnight ago. The patient was etherized; a probe passed in failed to detect the tube. The sinus in the eighth intercostal space was then dilated and dressing-forceps, straight and curved, were used without success. To give more room, one inch of ninth rib removed as follows: An incision, two inches long, was made down to the bone, the periosteum stripped, and a portion of rib gnawed away with rougeurs and Langenbeck's gouge. Some care was necessary in order to press back periosteum and pleura. The original sinus was then enlarged by lateral cuts of intercostal tissue, and two stout ligatures were passed into cavity by means of aneurism-needle introduced at either side of wound, and brought out in ninth interspace near cut end of rib. Thus the pleural subcostal periosteum and vessels were included and tied. The parts between were then cut through well into ninth interspace without any hemorrhage. The finger now introduced detected the tube parallel to spine, and a finger's length from opening. It was readily fished out with a stout bent probe and forceps, and found to be seven inches long.

In conclusion he adds, the accidental introduction of a drainage-tube into a cavity, which it is designed to empty, ought not to occur, if its end external to the

[1] Both cases presented at meeting of the New York Medical Union.

wound be transfixed by a safety-pin or needle, which will lie flat on the skin, and should not cross the lumen of the tube (MEDICAL RECORD, 1882, vol. xxi., p. 172).

CASE VII.—Dr. J. M. Hobson, in a detailed account of seven cases, treated antiseptically, states that in dressing No. 5 a second time, he found that "the tube had got into chest." Not stated how it was removed. "To prevent the tube slipping into the chest again it was transfixed with a needle, the point nipped off, and a strip of gauze interposed between its ends and the skin" (London *Practitioner*, 1882).

Dr. William B. Cheadle, Physician to the Hospital for Sick Children, Great Ormond Street, London, recommends as the best form of drainage-tube a modification of Baker's india-rubber tracheotomy tube. The flange prevents the loss of the tube into the pleural cavity—an accident which has occurred more than once with a portion of common tubing; once, perhaps more often, this has led to a fatal result (*Lancet*, American reprint, 1882, vol. i., p. 139).

CASE VIII.—At a meeting of the Société des Sciences Médicales de Lyon, Conette presented a drainage-tube removed from the pleural sac. A large tube was introduced after the first had entered the cavity. In some extraordinary manner the smaller tube got into the lumen of the second and was thus readily removed. Truly a remarkably fortunate occurrence (*Lyon Médical*, 1882, No. 20, p. 53).

CASES IX., X., XI. and XII.—Martin Oxley, in an article on "Pleurisy with Effusion" (*Liverpool Medico-Chirurg. Journal*, January, 1882), remarks: "If an ordinary drainage-tube is used, care must be taken to prevent its falling into the cavity of the pleura. This has happened on several occasions." He refers to a case reported by Dr. Wyglesworth, no bad result following. In the "Appendix of Illustrative Cases" four cases of foreign body in pleura are added. 1. In Dr. Durham's case a piece of linen was drawn in by violent inspiratory movement; removed by a pair of slender forceps, designed for removal of foreign bodies from the œsophagus. 2. In Mr. Brudenell Carter's case, a tube—six inches long—slipped into chest and remained for seven years without giving rise to symptoms; discharge still going on through another tube. 3. Dr. S. Thompson, gum-elastic catheter in chest for seven months, giving rise to no special symptoms referable to it. 4. Dr. Pugh, five inch drainage-tube slipped into chest; the opening closed; and two and a half years afterward the man is in good health.

CASE XIII.—Under the long heading "Extraction sans opération sanglante d'un tube à drainage tombé accidentellement dans la cavité thoracique, dans un cas de pyo-pneumothorax ancien, du côté gauche, avec persistance d'une fistule cutanée au point où avait eu lieu l'évacuation artificielle d'un abcès pleural," M. Duboné reports a case occurring in a male, twenty-four years old. One day while the patient was introducing the tube, it suddenly slipped in, in consequence of a deep inspiration provoked by a violent fit of coughing. The patient's condition was such (having had the fistula for six or seven years) that operative measures could not be used. Health became worse and worse, and the following plan was adopted: An elastic rubber cord covered with silk (about 50 ctm. long, diameter No. 5, Charrière) was folded into two equal parts. The looped portion readily entering the fistula was first introduced, then the rest was introduced once or twice daily into the thoracic cavity, 3 to 4 ctm. of each extremity remaining outside, and then slowly withdrawn, the idea being that as the cord was pushed into the cavity, its inherent elasticity would cause it to spread out and act as a snare. After fifteen days' trial (repeated once or twice daily) the tube was caught (one end appearing in the wound) and readily removed. The tube was 76 mm. long, diameter No. 10, Charrière, and though fifty days in chest it had not changed any (*Bull. et Mém. de la Soc. de Chir. de Paris*, 1882, pp. 571–574). It is difficult to say, which to admire most, the ingenious plan or the patience and perseverance of the physician.

CASE XIV.—Weir, in a clinical lecture delivered at the New York Hospital, refers to a case of his in which a rubber catheter, introduced to effect drainage, proved defective and broke off, so that one end of it remained loose in the pleural sac. For this reason a free incision was made through the chest-walls in order to remove it (*New York Medical Journal*, December 29, 1883).

CASE XV.—Dr. A. Caillé kindly favors me with the following: Child, sixteen months old; empyema of right side; chronic pneumonia of left side. Incision in eighth space; eight ounces of pus escaped, and cavity washed out with Labarraque's solution. Medium-sized drainage-tube (rubber) introduced and fastened with a safety-pin. The latter was a source of much irritation to the child, and induced me to split the end of the tube and stitch to skin with strong silk about two weeks after the operation. The child rested well after this. A week later the parents came to my office and asked me to hunt for the tube, which had probably slipped into the thoracic cavity. I introduced a "hook pincette" and succeeded in grasping the tube at the split end and withdrawing it. The silk had cut through the skin, but not through the tube.

CASE XVI.—To Dr. Martin Burke I am indebted for a brief history of a case occurring in the practice of Dr. J. Burke. N——, thirty-five years of age. Pleurisy, pus, drainage. Two weeks after incision patient carelessly took off strings which were attached to the plasters. Tube slipped into chest cavity. No operation would be consented to. New tube introduced. Five days after, patient had a violent fit of coughing, and both tubes were expelled through the incision. Patient made a good recovery.

CASE XVII.—Dr. J. L. Morrill kindly communicated the following: B. W——, male, eight years of age. June 26, 1882, an empyema of about two months' standing was operated upon by incision. A soft rubber drainage-tube, ten inches long and a quarter of an inch in diameter, was inserted and firmly fixed to a bandage around the body. July 1st, while dressing in the water-closet, the patient declared that the "tube had dropped into his body." The doctor, however, concluded that the boy was mistaken, inasmuch as the tube was bent upon itself at right angles, with more than half upon the outside, and securely fastened to the bandage. In the absence of positive evidence another tube was introduced and developments awaited. August 8th: Sent to country; gained nine pounds in ten days, and could walk about five miles daily. Tube removed August 26th, and wound healed at once. Patient frequently examined during the following months. The lung had expanded, vesicular breathing present to base; some pleural thickening. About the middle of the following May he took cold and developed a bronchitis of the right side. May 26: Was taken with a chill, fever, cough, and pain in the left side. Subsequently an empyema of the left side manifested itself. August 5, 1883: Drs. J. R. Leaming and White were called in consultation and an immediate operation advised. The new trouble being attributed to the presence of the tube which had fallen into the chest eleven (?) months before. August 6, 1883: Under ether an incision two inches long was made in the ninth intercostal space, and the pleura opened; thirty-two ounces of fetid pus escaped. The little finger was then introduced, and in a mass of thick pus and broken-down clots the tube was found in the most dependent portion of the chest. No adhesion or encystment. The boy was turned on his back, the tube brought to opening and removed with a blunt hook. September 17th: Nothing could be injected into opening; wound allowed to close. Patient perfectly well at date of this report, October 10, 1884.

CASE XVIII.—Yesterday (October 13, 1884) I had the pleasure of witnessing Dr. J. L. Little operate, and re-

move two drainage-tubes from the chest of a patient with empyema, at St. Luke's Hospital. The following are the main points in case: Male, thirty years of age. Was aspirated twice (five and three quarts of pus being withdrawn). In April, 1883, Dr. Burchard made an incision about two inches in length in the eighth intercostal space—eleven quarts of pus escaping. Two drainage-tubes were then introduced, and the extremities made fast by ligatures fastened to strips of adhesive plaster. The next day it was found that the adhesive plaster had become softened by the discharges, and the tubes had disappeared. The surgeon in charge searched for nearly two hours without finding them. At the consultation held next day it was decided that as the patient was doing well, and as the cavity was large, it was best not to attempt further search until the cavity had contracted. Two months after the patient passed from under the doctor's care. When presented to Dr. Little, eighteen months after the first operation, the daily discharge amounted to about one-half pint. On introducing the probe it came in contact with a tube. About an inch of ninth rib was excised, and the drainage-tubes were removed without much trouble. The tubes were three-eighths of an inch in diameter—one was eleven and one-half inches, and the other nine inches in length, and had been in the chest for eighteen months.

Case XIX.—At a meeting of the New York Surgical Society, Dr. Stimson said he had once occasion to remove a drainage-tube about one inch long from the pleural cavity, into which it had slipped after the breaking of the string by which it was secured. He removed a portion of one rib and seized the tube with a long forceps.

In an exceedingly elaborate, exhaustive, and learned discussion, extended over a number of months at the Academy, and reported in the *Bulletin de l'Académie de Medécine*, Paris, 1872—"Sur la Thoracocentèse"—the following cases are referred to:

Case XX.—M. Béhier removed a rubber bougie from the thoracic cavity of a patient with empyema, at La Pitié after incising an intercostal space. Patient recovered (p. 383).

Case XXI.—M. Richet was called in consultation by M. Beonutz to see a case of empyema in which a rubber bougie had escaped into the pleural sac. Removed through an incision in third intercostal space (*de bas en haut*). Recovery (pp. 479, 494, 700).

Case XXII.—Dr. Labric successfully removed a rubber tube from the chest of a child by means of a pair of curved tracheotomy forceps (La Thèse de M. Voyet, February 2, 1870, p. 43, *Bulletin de l'Académie*, 1872, pp. 479, 624).

Chassaignac has made it a rule to pass a cord through the entire length of the drainage-tube, and tie the ends externally, whenever the rubber is poor in quality (*Bulletin de l'Académie*, 1872, p. 482).

On page 552 he says: "The use of the elastic fenestrated tubes (*en forme de tube annulaire*) prevents an unfortunate but not infrequent accident, the escape of the tube or canula into the chest it is designed to drain."

Case XXIII.—Duplay ("Pathologie Externe," fasc. 3, p. 501) has seen a patient operated upon for empyema, in whom the long rubber bougie, which had been placed in the wound, entered the thoracic cavity. It occasioned so little inconvenience that he would not admit the reality of the accident, though it was evident that the tube could not be anywhere else than in the chest.

Case XXIV.—Rubber tube in right pleural cavity. The wound was dilated with a tent and long curved forceps, introduced by M. Peyrot. . . . Returned to the hospital later (une 2e fois chute du tube en cavité), it was impossible to seize the tube with dressing-forceps introduced into the wound. The patient was then turned, so that the aperture was dependent, the forceps were then introduced, and readily caught the foreign body (Dupuy, "Des Soins à donner aux operés d'empyèmes," Th. de Paris, 1876).

Case XXV.—M. Toussaint (médecin aide-major de 2e classe) reports the following: L——, twenty-two years of age, soldier; tapped several times (4 litres of sero-purulent fluid withdrawn, then 1,250 grm.); diphtheria of fauces, etc. June 5th, punctured with hydrocele trocar, and a fenestrated elastic tube introduced through canula; 900 grm. pus removed, and pleura washed out. As fistulous opening gradually enlarged, a tube, size No. 20, Charrière, was then introduced. General condition, better; vesicular breathing heard all over anteriorly. July 1st, when about to wash out the chest, it was found that tube had escaped into the pleural cavity. The little finger was introduced and forceps passed in various directions. Fistula then dilated. Next day a variety of forceps were passed in different directions by M. le Médecine-principal Poucet. The cavity was then injected, and patient so placed that fistulous opening would be at the most dependent portion. Then finger introduced. The patient's condition counter-indicated any further trials. A diaphragmatic purulent effusion subsequently formed on the other side. Though aspirated a number of times (1,200, 600, 310 grm. being removed), the patient died November 17, 1880, his death being preceded by hectics, colliquative diarrhœa, œdema of lower extremities, etc.

At the autopsy the inferior third of left lung was adherent in front, posteriorly, and in neighborhood of fistula. In front, and a little below the fistula, the tube was found angularly bent upon a bridge of new tissue about the size of the little finger. One side of the angle ran parallel to the sixth rib in a cavity with thick, fibrous walls, formed inferiorly by adhesions between the diaphragm and parietal pleura. The other side was lying transversely in a cavity shaped like the finger of a glove formed by the lung itself. These two sacs contained about 60 grm. of pus. Lower third of lung was hepatized, and presented some spots of cheesy pneumonia—no tubercles (*Rec. de Mémoires de Méd. de Chirurgie et de Phar. Militaires*, No. 205).

Dr. H. Kretz, in a personal communication, informs me that he succeeded in removing two rubber tubes from the chest of a child.

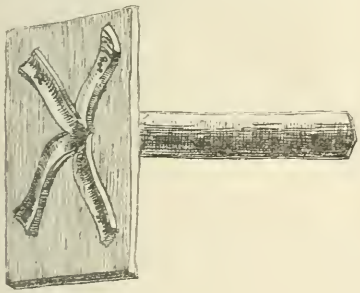
The original wound was incised, but the hemorrhage was so profuse that it became necessary to plug the opening. Subsequently he introduced an endoscope, and was thus able to locate and readily remove the tubes from the upper and posterior portion of pleural cavity.

Drainage-tubes.—Before proceeding further it may be well to spend a moment in considering drainage-tubes. Most surgeons have their individual preferences: the result is, that a variety of ingenious and excellent devices have been developed. Tubes of metal, india-rubber, hard rubber, or glass, may be used. Metal spirals and drainage-probes have their advocates. India-rubber tubes, first systematically resorted to by Chassaignac, possess many advantages over the costly, unyielding, metallic instruments. They are flexible, non-irritating, readily made, and easily manipulated, and form an inexpensive and universally applicable means of drainage. Ordinarily we employ rubber tubing of different diameters (red, not containing free sulphur is preferred), perforated laterally at short intervals (diameter of each opening being about one-third circumference of the tube. The outer end is cut flush with the skin. To keep the drainage-tube from slipping into the cavity, a variety of methods have been advised.

Mechanism of process.—Aside from sheer carelessness and the use of poor and defective tubes, the accident may occur in consequence of imperfect methods of fastening tube, and second, inward traction. The latter, in my mind, is the prime factor in many cases. Goyder (Senior House-Surgeon, Newcastle-on-Tyne Infirmary) found in treating a case of empyema by "respiratory irrigation," that one-half ounce of fluid was drawn up at every normal inspiration, and four ounces in deep inspiration, the tube used being eighteen inches long and three-quarters of an inch in diameter (*Lancet*, 1881,

p. 406, American reprint). Not only may the tube be sucked in during forced inspiration, but if a long tube be used, a further force, exerting a more gradual effect, is brought into play. On the latter ground only can I explain the accident in my case. It seems to me plausible to presume that a long tube may be caught between the chest-wall and the lung, which is expanded with each inspiration, at the same time the other extremity is carried upward and outward by the movements of the ribs; thus a certain amount of traction is put upon the fixed portion of the tube external to the wound. This process is repeated with each inspiration. The result is a yielding of the weaker portion. In my first case the plaster, loosened by the pus, no longer afforded protection, and the tube was gradually drawn in. In the second case the safety-pin gradually cut through the rubber, and thus allowed the tube to slip in.

Prophylactic means.—In view of the disadvantages and danger attending the use of the ordinary tube, numerous modifications have been adopted. A simple, efficient, inexpensive, and safe tube was suggested by Dr. E. Buchanan Baxter, of King's College Hospital. "A round hole is first cut in a piece of red india-rubber sheeting one-twelfth of an inch thick, and about one and a half to two inches square. A tube of the size required, and without holes, is then split at one end into four pieces, which are drawn through the hole in the flat piece of rubber, turned down and fixed in position by stitches of fine silver wire." The tube should be just long enough to project into the chest cavity—one and a half to two inches—according to the thickness of the chest wall. Nothing is gained by curling up an enormous length of tubing in the chest. Such a tube adapts itself to a sinus leading in any direction, and requires no special manœuvre to prevent it entering the chest (Godlee, *Annals of Anatomy and Surgery*, July, 1883, vol. viii.). These tubes can be made in a few minutes, of any size required, by the physician himself.



Ought the removal of the tube accidentally lost in the pleural cavity to be undertaken in every case? If so, what methods may we resort to, in order to accomplish this object?

These questions come up naturally. If allowed to remain, the tube may be encysted; second, may give rise to an intractable fistula; or third, may set up new inflammatory action. Though encysted or innocuous for the time being, the tube may give rise to trouble in the future. In the literature of antiseptic surgery we meet with instances in which a rubber tube, accidentally overlooked in the wound, has not given any evidence of its presence until an abscess form, followed by the discharge of the offending body.

O. Eyselin reports a tube, seven centimetres long and three-fourths centimetre diameter, overlooked in a case of deep-seated suppuration in right lumbar region (the thread fastening it having been broken). There was no complaint for nearly seven months. When four months advanced in second pregnancy an abscess formed in the lumbar region, broke, and to the surprise of the doctor and patient, the tube appeared, and when removed was found unchanged (*Berl. klin. Woch.*, 1881, xviii., p. 476). In this connection the case or Dr. J. L. Morrill is particularly interesting. "The wound had all healed, and during eight months there was absolutely no indication of the presence of the tube, and had he not taken cold or contracted some other disease that would light up the old trouble, it might have been there to-day."

Radek and Toussaint have reported fatal cases. Cheadle says once, perhaps more often, this (loss of tube in chest) has led to a fatal result:

The dangers attendant upon long-continued suppurated processes are well recognized and understood. The cause must be removed. The same rule of surgery ought to guide us in cases of thoracic fistula due to the presence of a foreign body. Remove the tube, which has escaped into the pleural cavity, as early as possible. Do not subject your patient to the danger of tuberculosis, waxy degeneration of important organs, or septic poisoning. New inflammatory complications arising from the presence of an irritant in the chest may place the patient's life in the greatest danger.

Thus we must necessarily admit the advisability of operative interference. As the various measures have been fully entered into in the cases reported above, I shall merely present the following resumé:

The simple methods should be resorted to first. If we are fortunate enough to see the case within a short time of the accident, before the position of the tube has been changed by cough or other movement, we may succeed in seizing the tube with forceps introduced into the wound. If the orifice be too small to admit the forceps, use a sponge-tent or dilator. In using the tent we must bear in mind the possible existence of a bony bridge of union between the ribs in chronic cases, the tract passing through an osseous ring. The attempt to enlarge such a sinus by means of a sea-tangle tent necessitated the removal of a portion of two ribs in a case reported by Godlee ("Annals of Anatomy and Surgery," July, 1883). In order to gain the "required sense of touch" it is advisable to pinch an india-rubber tube with forceps, before blindly searching the cavity.

If we fail after passing forceps of various kinds into the thoracic cavity in different directions, the patient should be placed in the horizontal position, the fistulous opening being most dependent, and then search again with forceps, bent probe, etc. This not succeeding, inject the cavity with water, in the hope that the return stream will carry the tube into the vicinity of the opening.

These means proving unsuccessful, the orifice should be enlarged with a knife so that the finger can be introduced. If the space be still too small, a portion of a rib must be removed in order to accomplish our object.

The patient's condition being such that operative means cannot be resorted to, we may avail ourselves, if we possess the necessary amount of patience, of Dubonè's plan.

Further, it is well to bear in mind that the adhesions which have occurred between the pulmonary and costal pleura in some cases will probably retain the foreign body in the neighborhood of the fistula, rendering the removal a simple and easy process. The case is apt to be more serious if the affection be recent; adhesions not having had time to form, the tube has probably gained the most dependent portion of the cavity, and will in all probability be found in the costo-diaphragmatic sinus. The complication is greater if the original incision have been made high up. A second opening in one of the lower intercostal spaces may be required before we can reach the tube in the chest.

In conclusion I would add, if an ordinary tube be used, thorough measures should be observed in order to avoid any accident. Poor material should be discarded; subject the tubing to the proper test—"it should bear being tripled in length without breaking" (Nicaise, *Revue de Chir.*, December, 1881). Inefficient means should be avoided. A strip of plaster, a pad of oakum, or other

dressing will not answer. If the patient be permitted to introduce the tube, warn him of the attending danger, and instruct him how to fasten the tube in a proper way. Remember that the silk threads attached to the tubes have been broken more than once. The safety-pin may cut through the rubber in other instances. The tube of Baxter, recommended by Godlee and Pilcher, is so simple, readily made, and safe, that I would insist upon its use in all cases. I have used it twice during the past six months, and have no fault to find. It answered its purpose fully, and is unattended with the danger of accidentally slipping into the chest. I cannot say too much in its favor.

SEPTIC PYÆMIA PRECEDING PARTURITION FOLLOWED BY METASTATIC CHOROIDITIS, ETC.

By S. H. HUNT, M.D.,

LONG BRANCH, N. J.

Mrs. B—— was delivered of a dead fœtus and a purulent placenta July 25, 1884. The case presented a train of unusual symptoms, made more noticeable on account of a similar result of labor which occurred one year previous (June 14, 1883). At that time it was supposed she had overrun the average period of gestation. Her appearance was peculiar on account of the unusual size of the abdomen, which pointed to a plurality of conception, but the event proved otherwise. But this conviction was not dissipated by the delivery of the child, as she still appeared to be of mammoth proportions. An examination (intra-uterine) showed an absence of any other fœtus, but revealed a mass on the fundus or side of the womb larger than a fœtal head. This was more discernible by external palpation and manipulation. Having delivered a woman of a living child weighing nine pounds who presented a similar condition, and had three large fibroid or intramural tumors, which accounted for her deformity, it naturally occurred at first thought that a somewhat similar condition might now be present. But this conclusion was gradually abandoned as the history of the case unfolded itself. In two or three days a discharge of half a pint of pus from the uterus awakened further investigation and inquiry. This discharge continued for some time, but gradually abated, the womb slowly assuming normal proportions under massage and intra-uterine douches. It was fully three months before it ceased to be noticeable, at which time but little sub-involution existed.

The patient had a tardy but complete restoration of health, and no untoward symptoms presented themselves. Before her return to the city, late in the fall, she informed me that she was again pregnant, and full of hope for a more successful accouchement the coming summer.

It was my misfortune to witness her disappointment on the day before stated. The authorities I had consulted during her first illness gave no history of an abscess occurring under such circumstances in the body of the womb, or rather in its muscular coat, and I was led to the conclusion it was one of those rare cases of salpingitis, or an abscess of the Fallopian tube which found its escape into the uterus. The cause was undoubtedly owing to a partially decomposed fœtus or a decomposing placenta.

The absorption of septic material may, as Virchow has shown, be delayed by the local changes produced in the lymphatics and in the glands with which they communicate, which are therefore conservative in their action, and the further progress of the case may in this way be stopped, and local inflammation alone result, such cases being believed by Heiberg to be examples of *abortive pyæmia*.

The subsequent accouchement of this lady was a confirmation of the conclusion that was reached during her first confinement. I was called to see her on July 22d, at which time she informed me that her labor was past due, and that 280 days had elapsed the preceding week since the cessation of her menses. Knowing full well that considerable variation is frequent where accurate records are kept, and that when labor is deferred it rarely interferes with the viability of the child, I endeavored to assure her on this point, as she appeared in perfect health. If her record was correct, it was not unusual or remarkable, in view of the many cases that have been reported. That its duration is oftener less than 280 days is indisputable, while some controversy has arisen as to its being prolonged beyond that time, but facts, which are stubborn things, prove it beyond a shadow of doubt. Desormeaux reports from a single coitus a case of 287 days; Lee, 287 days; Beatty, 291 days; and Skey, 293 days. McIlvain reports one 293 days, and another 296 days. Ashwell, 300 days, while Asdrubali believes a pregnancy of 13 months and 22 days, and Meigs that 420 days does not vitiate chastity. In The Medical Record, November 22d, Dr. J. W. Wright reported and substantiated a case in which the duration of pregnancy was 330 days. The lady was delivered of a living child weighing 11½ pounds, the time of parturition being only three hours. He further states the longest case he was able to find was reported in Leishman's "Midwifery," and was 332 days.

July 24th.—Mrs. B——'s condition was good, and promised well until the evening of this day, when she was taken with a heavy and pronounced chill lasting about twenty minutes, followed by a burning fever with a temperature of 104½°. She complained very much of burning of the skin and the terrible irritation it produced. I have rarely seen the capillary congestion so intense and so pronounced.

This new and unexpected development awakened the alarm of her husband, and Dr. James B. Hunter was called in consultation to consider the feasibility of producing labor, which he deemed inadvisable, and it was therefore deferred. I was called at twelve o'clock the same night and found labor had commenced. The temperature had fallen to 103°. I delivered her of a dead fœtus slightly changed in appearance. The cord was dark and fragile. The placenta, which was intact, presented a peculiar appearance. Its surface, where it had been attached, looked like a grayish sloughing ulcer, and quite a quantity of apparently purulent matter followed its removal.

John Hunter is reported to have taught that the separation of the ovum from its temporary lodging-place in the uterus involves what is equivalent to an extensive wound, healthy and well-disposed, and nearly always equal to its own cure. The wound left in this case, from the appearance of the detached placenta, must have been unhealthy and ill-disposed, and judging from the placental tufts it was a sloughing wound and the foci of the septic absorption that was ushered in by a chill before parturition commenced. It was without doubt autogenetic. The labor was a comparatively easy one, lasting but six hours, though she required some assistance. Her thirst could not be assuaged, nor the fever allayed. I visited her again at midday and found that a thoughtless woman had carelessly opened both windows and the door, and a strong draught from a cold raw and chilly northeaster was sweeping over her. This was done at her urgent solicitation to allay the burning heat of her face and body, which she said would set her wild. Quinine was given, thirty grains daily, and intra-uterine douches of bichloride of mercury, while vaginal douches of carbolic acid were frequently made.

July 26th.—She complained of pain in the left knee and shrieked with its every movement. It was swollen, and several fiery red spots attracted attention. My worst apprehensions were about to be realized. On the same day the right eye was violently inflamed.

June 27th.—Fever varied during the day from 102½° to 103½°, but no more chills were experienced: knee was

more swollen, and the left arm became useless from a similar cause.

July 27th.—There was a slight abatement of the fever, but the orbit of the eye was pressed out by the intra-ocular effusion, which ruptured the conjunctiva and allowed it to hang in serrated folds on the cheek. It was unmistakably metastatic choroiditis, and the rapid inflammation soon resulted in purulent effusion pushing the lens forward into the anterior chimney of the eye.

July 28th to 30th.—The lochia came on profusely and was of a bright arterial color for several days. There was no marked odor of the lochia, nor were there any symptoms of metritis or peritonitis. The abdomen was not tender on pressure, nor was there any tympanites. The fever continued with slight variations, and the new foci of poisoning showed themselves in the lymphatic glands of the neck, which became enormously swollen. The right limb became also affected, and only anodynes alleviated her sufferings. There was no secretion of milk in the mammary glands, and they were flaccid and unenlarged. She was given with quinine the bichloride in minute doses, and the douches were continued. Her appetite continued fair, and a liberal diet of eggs, milk, and the juice of broiled steak, with milk-punch, constituted her diet.

August 1st to 3d.—Her symptoms grew gradually worse. There was sordes, her mouth was coated with a thrush-like exudation, and the stringy, tenacious secretion was with difficulty wiped from her swollen lips. She now became at times delirious, while the swelling of the joints partially subsided, but her strength was gradually failing her. The eye had suppurated and no symptom of septic pyæmia was absent. Drs. Hunter, Riley, Smith, and Hughes saw the anomalous case with me, and all gave a fatal prognosis.

August 3d to 7th.—She was now in a low typhoid condition, and had to be aroused from her stupor to take nourishment. Still, despite this, every time she was lifted on her pillow she groaned from pain. At this time there was a slight enlargement of the abdomen, while a profuse diarrhœa which came in frequent and overwhelming gushes added to her misery and discomfort. It was temporarily checked, but returned again, proving how thoroughly the mucous membrane of the intestinal tract—her whole system, in fact—was poisoned by the septic matter. This very estimable lady, of many graces and accomplishments, gradually sank from exhaustion, and died on the tenth of the month—seventeen days after her confinement.

A Simple Expedient in the Management of Strangulated Hernia.—A correspondent who has forgotten to attach his name to his article writes calling attention to a simple expedient that he has resorted to successfully in cases of strangulated inguinal hernia after taxis had failed. It consists in dilatation of the constriction which produces the strangulation at the internal abdominal ring by passing the finger along the inguinal canal, carrying the integument before it until the constricting ring is felt, which generally is easily done; the finger is then gently insinuated into the opening, and if the band of opposing fibres does not yield readily, gentle pressure is made against the upper border of the ring until it is felt to give way, when a resort to taxis again will ordinarily result successfully.

The advantages to be gained by this expedient are that it can be tried as soon as moderate efforts at taxis prove ineffectual, and before the tissues involved are injured by prolonged or severe manipulation; the patient is saved from the dangers resulting from delay; and the dangers attending operative interference, with the complications and sequences which may arise therefrom, are supplanted by a procedure which is harmless in itself and is not liable to be followed by any complication.

Our correspondent finds that there is no danger of creating a larger permanent opening at the internal ring. He has tried it in five cases.

PURPURA HEMORRHAGICA.

By JOS. HAV. ZITEKE, Ph.D., M.D.,

NAPOLEON, IND.

The quick and fatal termination of the following case of purpura hemorrhagica, its strange course, and the absence of all the common symptoms of the malady, lead me to submit its history to the notice of the medical profession at large.

Mr. Johnson M——, a farmer, living about three miles from our village, called upon me toward the end of last June, in order to consult me about some spots which appeared a few days previously upon his arms and legs, and caused him considerable uneasiness.

The spots were but few in number, of red color, which by and by changed into a purplish hue, and became surrounded by a yellow-greenish aureola. His general state of health was excellent; his appetite and his digestion good, his bowels regular, his sleep healthy—in short, he considered himself well in every respect, except the eruption.

I told him he was suffering from purpura hemorrhagica, and knowing but too well that he indulged very often in alcoholic drinks, I advised him to stop drinking and eating of old salty pork, take more light and vegetable nourishment, and use lemons in large quantities for some time to come.

The advice given did not suit the man, for I saw him during the following two weeks several times in one or another of our rather too numerous saloons, and sometimes far from sober.

About three weeks later he called again, and said he had consulted Dr. I. Anderson, one of the most able and respected practitioners of Ripley County, and had asked his advice. The doctor told him it was purpura, and advised him to use "iron tonic" and to take good care of himself, as the disease was dangerous. He had followed the advice of the doctor, used two bottles of iron tonic, but, instead of getting better, he grew weaker, and for some days had been bleeding from his gums.

On this occasion I examined him carefully, but could detect no disease whatever.

Stat. præsens.—The patient was a tall, muscular man, with very little of adipose tissue, but firm muscles and strong bones. His age was about fifty-six years, and his height nearly six feet. His skin was of a slight yellowish hue, his hands and feet covered with about ten to fifteen small lentil-formed carmine-red spots, and about as many dark purple petechiæ with large aureolæ of green-yellowish color. Heart and lungs were normal. His pulse was full and 75 per minute. His urine was tested for albumen and sugar, but the result was negative. No epithelial casts were present. The specific gravity was 1.020; the color light yellowish; the reaction slightly acid.

Examination of his past life revealed nothing. He was never sick. Even at that moment his appetite was good, his digestion perfect, his bowels regular, his sleep sound. No cough, no dizziness, no headache, no frequent micturition—in short, he felt all right, only a little weak, and bleeding from his gums, which had the common, infiltrated, spongy, scorbutic appearance.

I repeated once more the advice I gave him, and gave him liq. ergotæ purificatus and a tonic mixture of iron and aromat. sulph. acid.

About a week later I was called to his house, and found him sitting on the porch spitting from time to time a large quantity of blood mixed with saliva.

There was no change in his state, no symptom to be detected, no pain to be complained of, except the increasing debility and the continued bleeding. I was surprised that the remedies prescribed produced no effect, for I had tried them many times before, and they never failed in their action, but said nothing, and gave the same remedies in increased doses. However, I soon found out the cause of the inactivity of my drugs, which

consisted in nothing but the impatience of Mr. M——, who, having taken two or three doses and feeling no better, discontinued them at once and consulted another physician, who proclaimed his case to be "Bright's disease," and gave him some remedies which were "sure to cure him." However, after a week of treatment for Bright's disease, the patient grew worse and sent for me again, as I have already stated.

Having given him the remedies, I ordered him to use them carefully and punctually, as otherwise he would surely die.

The next day his son called at my office and told me the bleeding had stopped, but his father felt awfully weak. I advised him to continue the medicines, as no improvement or cure were possible but in the course of several weeks.

From that day on I never saw the patient again; for Mr. M——, disgusted with the slow treatment, took my medicines but for two days and sent then for another physician, who said the disease was a "lung trouble," and promised speedily to cure him. Having taken some of the medicines prescribed by this doctor, Mr. M—— was obliged to retreat to bed, which he never left, dying in about eight days later. If our county papers are to be trusted, the death certificate was "Death by Bright's disease."

Interested as I was in the case, I inquired about the symptoms of the last eight days of his sickness, and his nephew, an intelligent young man, said that from the moment he was confined to his bed till his death, he never coughed, had no fever, ate sufficiently, passed his water four or five times in twenty-four hours, and complained of no pain whatever. Only about an hour before his death he seemed to suffer. The petechiæ appeared also on his chest during the last week of his sickness.

The entirely painless course of the disease, the sudden death, and the impossibility of detecting any important organic disease, were facts which seemed to merit the placing the whole case on record. While practising in Austria, and later in Northern Germany, I have often had opportunity to see and to study cases of purpura hemorrhagica and morbus maculatus Werlhofii, but the prominent symptoms of all those cases were quite different from this one.

Thus in the districts of Northern Germany, where large quantities of brandy-wine are fabricated and consumed, I saw several cases of purpura, in cachectic subjects, debilitated drunkards, and persons suffering from cirrhosis, chronic nephritis, or Bright's disease.

Even here I saw but a few months ago a case of Bright's disease (Mr. D——) accompanied by slight purpura, but profuse hemorrhage of the gums, which appeared at the same time as the general anasarca, and lasted till the death of the sick man. In that case all the symptoms of Bright's disease were evident, and the chemical test of the urine confirmed the diagnosis.

And again, in cases of morbus maculosus Werlhofii, I never saw the patient bleeding from gums presenting the well-known infiltrated, spongy, scurvy appearance. Besides, the slow formation of the purpura petechiæ was always preceded by slight derangements of the digestive apparatus and a general debility and weakness of the constitution, while in the case of Mr. M—— the purpura appeared without any previous and warning symptoms, and was followed by a slight weakness, which did not prevent him from attending to his business at all.

Dr. Leloir published some time ago, in the *Annales de Dermatologie et de Syphilis* two cases of purpura, each of a different nature.

The first was that of a man, fifty years of age, suffering from inveterate syphilis, cirrhosis of the liver, and œdema of the extremities, who died of bilateral pneumonia. The post-mortem examination of a portion of the skin furnished a splendid picture of the changes caused by œdema in the skin, while the pathological changes as to purpura revealed but an enlargement of the capillary vessels, most conspicuous in the papillæ, which were considerably enlarged, even to fifteen or twenty times their former diameter. The external side of their walls was covered with numerous white blood-corpuscles. On places where the hemorrhagic infiltration took place all the vessels were strangely changed, the greatest and most conspicuous being in the endothelium. The epithelial cellulæ were lodged in four to five rows, and had on some spots a tendency to rise into the blood-vessels and thus to obstruct their lumina. Around the altered and obstructed vessels spots of extravasation were found, which though small in circumference were nevertheless very numerous.

The other case of Dr. Leloir was a subject in the last stage of phthisis, on whom the purpura appeared during the few last days of his sickness. The petechiæ were observed only on his extremities, which were slightly œdematous. The pathological examination revealed tuberculosis, dilatation of the heart, and partial fatty degeneration. The microscopical examination of the skin proved that the seat of the hemorrhage was in the central portion of the skin. The blood-vessels of the papillæ were normal and, even in the central portion and in the seat of the hemorrhage, unchanged, though in some few places enlarged. Meanwhile, the greater part of the blood-vessels of the central portion, and even some of the deeper ones, had their lumina closed by clots of fibrin. The blood examined showed a considerable diminution in the number of red corpuscles. Dr. Leloir explains the appearance of purpura in this case by formation of fibrin clots, which took their origin in the cachectic condition of the blood, and having closed the lumina of the blood-vessels, produced the hemorrhagical infarct upon the skin.

The first case, according to Leloir, is a case of purpura caused by the diseased condition of the vessels, the other by the cachectic condition of the blood itself.

Other cases of purpura reported more recently, were those of Dr. Schwartz, of Vienna, in which purpura appeared in company with an insufficiency of the valves of the aorta, and those of Dr. Morel-Lavallée, where purpura was seen in consequence of using chloroform (*Wiener Medicinische Wochenschrift*, No. 32. 1883. *Annales de Dermatologie et de Syphilis*, No. 2, 1884).

Some attempt at a classification of purpura was made by Dr. Mathieu in the *Archives Générales*, September, 1883, where it was stated that hæmophilia, morbus maculatus Werlhofii, and purpura produced by arthritic and rheumatic cachexia, by infection and poisoning, are nothing but a common symptom of several diseases, which he calls purpura cachectica, and which general term he subdivides into the following classes: 1, That produced by progressive anæmia; 2, that produced by tuberculosis; and finally, 3, the hydropignous or nephritic cachexia, following Bright's disease. The chief cause of the first class is pernicious anæmia, in which the physio-pathological state of the spleen is of the greatest importance.

Purpura which accompanies tuberculosis, and is sometimes called neuropathic purpura, has its origin in the diseased condition of the nervous system, and is found mostly in subjects with a hæmophilic or hemorrhagic diathesis.

As to the hydropignous cachexia, the hemorrhagic diathesis is as often found as anasarca or œdema. Similar to the purpura of Bright's disease is the purpura senilis, characterized by its long duration, its appearance on some favorite spots (as dorsum manuum et pedum), and its small petechial form without an aureola.

The short synopsis of the opinion of Dr. Mathieu can be given as follows:

First.—Pernicious and excessive anæmia, has as its characteristic sign general want of blood, often repeated œdematous swellings, hemorrhages, and its similarity to cancerous cachexia.

Second.—Purpura accompanying phthisis or tuberculosis pulmonum is caused by some secondary disease, as

meningitis, hepatitis, cirrhosis, yellow fatty degeneration, etc.

Third.—Purpura accompanying Bright's disease is not uncommon—yea it can often lead to detection, or perhaps to confirmation, of a doubtful diagnosis.

The prognosis in such a case is, however, always fatal. Cardial cachexia may also be accompanied by purpura, in which case it is usually caused by a general sclerosis of the arteries, or by icterus, albuminuria, etc., in which case it spreads all over the body. If it is, however, only local, or covering the extremities, it originates from embolism, œdema, or some local obstacle in the circulation.

As to its form and shape, it appears both in the form of petechiæ or ecchymoses, which sometimes may cover a large circumference. The papular or erythematous form, however, is never observed in such cases. Such is the synopsis of the classification of purpura hemorrhagica by Dr. Mathieu.

To return, however, to my own case, I can but say that the absence of all physical and pathological symptoms, and the impossibility of examining the blood or skin of the deceased chemically and microscopically, made me quite unable to place the disease into any class whatever, and obliged me to design it by the simple name, purpura hemorrhagica.

In conclusion, however, I cannot help saying, that if the statistical tables of Indiana are based upon such an accuracy as was done in this case, and as I observed in at least ten other cases, I think the time and money expended worse than useless, and do not wonder that Dr. Elder, the Secretary of the State Board of Health, does not look upon them with full confidence.

Progress of Medical Science.

Naphthalin in Various Intestinal Diseases.—The success attending the employment of naphthalin in diarrhœa was recently noticed in our columns. In the *Berliner Klinische Wochenschrift*, October 20, 1884, Rossbach relates his experience with the drug in a variety of intestinal disorders. He now regards it as the best of disinfectants for internal use; indeed, it was from its action on the process of putrefaction in the intestine that he was led to employ it, not only in diseases of this organ, but also in those systemic maladies which affect especially the intestinal tract. The drug must be given in a purer form than that usually found in the shops, and it is advisable to wash it with alcohol until this flows clear. His favorite prescription is as follows:

℞. Naphthalini purissimi,
Sacch. albi.....āā gr. lxv.
Ol. bergamot..... gtt. j.

M. F. pulv. divide in part æq. No. xx.
S. from five to twenty powders during the day in wafer.

In tubercular affections of the intestine he has used it uninterruptedly for weeks without any ill effects. When a sufficient quantity of naphthalin is given the stools become almost odorless. In long standing catarrh of the small or large intestine, with or without ulceration, the drug has, in the author's experience, given the happiest results. In acute diarrhœa it acts well, but as this disease is self-limited and so well controlled by opium, its employment is not urged. In the summers of 1883 and 1884 a large number of children were treated for cholera infantum. Those treated with naphthalin in doses of one to three grains, every two hours, appeared to do as well, at least, as those treated with calomel. When given in small doses in typhoid its effects were not marked, but when the dose was increased some cases were seemingly aborted in five or six days, and others appeared much benefited. Judgment is reserved on the beneficial effect of the drug in tuberculosis of the bowels, but in the present helplessness of medicine in this affection it may well be tried. Finally, arguing from its undoubted benefit in most intestinal diseases, the author advises its trial in large doses in the premonitory diarrhœa of the first stage of cholera.

Uræmia.—The pathology of uræmia reminds one of attempts to thread a needle in darkness, the distance of the point of the thread from the eye of the needle being very difficult to determine. One year we are informed on good authority that urea may be injected into the system without serious results, and the next year the direct opposite is affirmed. This is but one aspect of this many-sided subject. The chief dispute in the pathology of uræmia is as to the nature of the toxic agent. Drs. Gréhant and Quinquaud have returned once more to the question, and in an experimental method (*London Lancet*). Subcutaneous injections of aqueous solutions of pure urea have been employed in gradually increasing quantities on frogs, guinea-pigs, rabbits, pigeons, and dogs. The result was constant for the different kinds of animals, and consisted in a more or less rapid death from tetanic convulsions, similar to those produced by strychnia. The most numerous experiments were performed on dogs. The toxic dose of urea in the blood was fixed with exactitude, and the influence of urea on muscular contractility was studied. Death always ensued when a dog received into its system 10 grammes of urea for every kilogramme of body weight, or in other words when a hundredth part of the body weight of urea was injected. The proportion of urea in the blood, as estimated just before or after death, was 6 grammes for every 100 grammes of blood, and this relative proportion obtained in all the other animals employed. In a case of anuria in a man the proportion was .410 per 100 grammes, and in another case of retention of urine, .278; in a case of interstitial nephritis, the patient suffering from uræmic dyspnœa, it was .210, and in a case of uræmic coma .215. Under the circumstances of the experiments all the tissues of the animals were impregnated with urea, so that 100 grammes of blood yielded 613 milligrammes of urea; 100 grammes of liver, 580 milligrammes; 100 grammes of cardiac tissue, 311 milligrammes; 100 grammes of spleen, 662 milligrammes. The observers always noticed that the urea injected under the skin was never completely absorbed, even at the time of death, though death might have been delayed for ten hours. By exposing the sciatic nerve and displaying the calf muscles, to the cut tendo Achillis of which a dynamometer was connected, the authors decided that uræmia does not increase or diminish muscular contractility. The blood of the dead animals, when submitted to distillation at a temperature of 40° C. *in vacuo*, furnished a liquid absolutely free from ammonia; the conclusion drawn from this experiment is that urea does not act as ammonic carbonate.

Paracentesis Thoracis as a Therapeutic Agent.—Dr. White (*British Medical Journal*, November 1, 1884) recently read a comprehensive paper on paracentesis thoracis. From the earliest period, no subject has excited more discussion, or has evoked greater divergence of opinion, than the treatment of effusion into the thorax. This divergence, however, while of late years much lessened, yet continues; and the profession is still far from unanimous as to the best methods of dealing with such cases of thoracic effusion as are found to resist routine treatment. The points which, according to the author, are of importance in treatment are these: 1. In pleuritic effusion, early evacuation of the fluid by the siphon principle, discarding the aspirator, is indicated. 2. In empyema, pus should be withdrawn at once, by the siphon or by the aspirator, with the use of the manometer, and the pleural cavity irrigated. 3. Incision is called for where large empyemata have existed for some time in old or rigid chests, or where irrigation, having been practised several times, has failed. 4. Where incision fails to effect a cure, resort must be had to resection of ribs. 5. Paracentesis, with drainage, should be employed in the treatment of lung-cavities.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 3, 1885.

THE GERMAN, ENGLISH, AND AMERICAN METHODS OF TREATING ACUTE BRIGHT'S DISEASE.

ACUTE nephritis is a disease which is by no means rare and which always occasions anxiety to patient and physicians. Its treatment since it was first recognized has undergone some changes, and at the present day there is a lack of complete unanimity as to the best methods to employ.

In a recent lecture upon the therapy of nephritis, Professor H. Nothnagel gives an interesting presentation of his views upon this matter.

As regards the *indicatio morbi*, we have, he says, an acute inflammation with which to deal. Unfortunately, however, we cannot apply the ordinary antiphlogistic measures. Cold is dangerous; venesection is also of no use and may cause harm; even the application of wet cups to the loins, as once recommended, should be avoided, except in sthenic cases where there is great pain. The patient should be put to bed and the room kept at a warm and equable temperature. His diet should be carefully regulated, and should consist of milk, soup, a little meat, but no vegetables and no alcoholic drinks.

There are no remedies, says Professor Nothnagel, which act upon the kidneys to influence the course of the disease. "Whether one gives them or not, it is just the same." In practice, however, he adds, it is necessary on psychical grounds, *solatii causa*, to prescribe something. Acetate of lead or ergot may be given in the hemorrhagic forms. These drugs stop the hemorrhage, but do not affect the course of the disease. Tannin, gallic acid, and nitric acid, as recommended by Frerichs, are of no real service. Of fuchsin, which has been much used by Italian physicians, we know only this, with certainty, that it colors the urine. Potassium iodide has not yet produced any certain results. Nothnagel does not seem to be aware of the value of digitalis or of the alkaline salts, as used by English and American physicians.

But, although drugs are useless, "the physician must not stand idle with his hands in his pockets." If the inflammation cannot be directly affected, it can be at least lessened or checked by derivative methods.

The bowels and skin are to be acted upon. Drastic cathartics or drastic doses of senna, bitter-water, or other salines are advised. These drastics, however, are only to be given in severe cases, when some uræmic symptoms appear. Ordinarily, laxatives are all that is necessary. It is most essential that the skin should be acted upon, and for this purpose hot-water baths, hot compresses, etc., and pilocarpin are indicated. Such are the views of the Vienna Professor.

Coming to this side of the Atlantic, we find that the latest expression of American views upon the treatment of nephritis differs from that of the Vienna clinician. In Professor A. L. Loomis' recent treatise on "Practical Medicine," the author reviews this subject of treatment by diaphoretics and hydragogue cathartics. He states that he has been convinced for some years that the depurative method was wrong, and gives as the three indications: the elimination of urea and its allies, the removal of inflammatory products from the tubules, and the counteraction of the effect of urea and its waste products upon the nervous system. For this purpose the patient is put to bed, frequent dry cups are applied over the loins, and infusion of digitalis is given internally. This may be supplemented with acetate of potassium, spirits of nitrous ether, or some other mild diuretic. The bowels are of course kept open, and the skin moist. If severe uræmic symptoms appear, hydragogue cathartics and hot-air baths may be temporarily resorted to. Milk should be the only article of diet, and water is the best diuretic.

The view taken as to the utility of digitalis and the potash salts in nephritis, is sustained by the clinical experience of nearly all English observers from the time of Bright.

We believe that it is no national prejudice, therefore, which makes us express the decided opinion that Americans are in advance of the Vienna physicians in the practical management of acute nephritis. But both Germany and America must pay tribute to the scientific acumen and practical sense of the English in this branch of therapeutics.

THE INJURIES CAUSED BY VACCINATION.

IT is, we believe, advisable to give the anti-vaccinators full opportunities to ventilate their fanaticism, the parable of the calf and the rope being most instructive in this connection. It is not to be denied either that these same anti-vaccinators have done some good in causing more careful investigations to be made into the value of vaccination, its associate dangers and the safest methods of its application. Thus do we get wisdom out of the mouths of babes. *A propos*, we publish a portion of a letter just sent to us by Mr. William Tebb, of London, bearing upon the subject of the dangers of vaccination. He says that an anti-vaccination committee recently sent out four thousand circular letters of inquiry to medical men, receiving three hundred and eighty-four answers in return. Regarding these replies, Mr. Tebb says: "A conspicuous feature is the large proportion emanating from public vaccinators, medical officers of health, and, in short, those whose practical connection with the subject entitled their replies to serious consideration. These number one hundred and two. The object of this communication, however, is to call attention to one revelation of paramount importance to the public, which I apprehend, few of the committee suspected when the circulars were issued. I refer to the disclosures made in answer to the

third and most pregnant question : 'What diseases have you in your experience known to have been conveyed, occasioned, or intensified by vaccination?' From a careful analysis made by Mr. T. Baker, of the Inner Temple, it appears that 10 medical witnesses certify to inflammation, 19 to phlegmon, 22 to erythema, 24 to skin diseases [*sic*], 47 to syphilis [?], 69 to eczema [!], and 122 to erysipelas. Of these, 33 *refer* to fatal cases. In all 40 diseases are specially mentioned by 242 medical practitioners as having occurred in connection with vaccination in their own experience."

Without explaining the inoculation of eczema, or the forty-nine cases of syphilis, Mr. Tebb proceeds in artless disregard of logic to draw a number of conclusions from these statistics. It is useless to argue with such minds as that which our correspondent represents. Vaccination protects, and vaccination, if carefully performed, is safe. These propositions are absolutely demonstrated, and are perfectly unassailable. We abandon, as idle waste of time, attempting to demonstrate them again for the benefit of fatuous ignorance.

SOME RECENT VIEWS ON THE SURGERY OF THE GALL-BLADDER.

THE feasibility of ridding the gall-bladder of accumulated calculi, as well as the possibility of relieving obstruction of the various bile-ducts, may at any moment present itself to the practitioner as a question calling for decisive action. It is but a few years ago, that Sims brought cholecystotomy into prominence and repute, and already the operation has been performed almost thirty times.

In an article, discussing this subject, which appeared in THE MEDICAL RECORD, of May 3, 1884, Dr. C. W. Allen recorded eight cases of cholecystotomy for the relief of gall-stones, with five recoveries, and one successful cholecystectomy, which had been reported up to that time.

Lawson Tait, in *The British Medical Journal* of the same date, reported thirteen cases successfully operated upon by himself. Nine of these had not previously been made public. In one case, published by him in the same journal, July 12, 1884, Tait opened the abdomen and crushed a stone in the common duct, the patient making a good recovery.

Langenbech's operation for the complete removal of the gall-bladder appears to have been done in six cases, three of which recovered. Nevertheless cholecystectomy, as advised by him, can have but a limited range of applicability. And certainly in case the stone obstructs the ductus communis, as it often does, preliminary or supplementary lithotrity would become a necessity.

Spencer Wells' operation consists in removing the contents of the bladder, closing the incision in its walls by a continuous suture, and returning the organ to the peritoneal cavity without attaching it to the abdominal wound.

Tait condemns both of these operations, believing that in ordinary cholecystotomy we have all that can be desired.

However, Dr. Gaston, of Atlanta, Ga., is not satisfied with the simple operation, as advocated by Tait. In a paper published in *Gaillard's Journal*, October, 1884, he proposes, as a substitute, to establish an opening between the gall-bladder and the upper division of the intestinal canal. He thinks that Spencer Wells' operation may prove adequate, provided it is followed up by a subsequent procedure, allowing the bile to flow into the intestine. This suggestion of Dr. Gaston's is not, as he supposes, an entirely new one. Over two years ago Dr. Winiwarter performed a successful operation for occlusion of the cystic duct, attaching the gall-bladder to the colon. The case is reported in the *Prager Medizinische Wochenschrift*, No. 21, 1882. Dr. Gaston has not hitherto had occasion to perform his operation on man; but he gives the result of some interesting experiments on dogs. In several animals he united the walls of the gall-bladder to those of the duodenum by means of an elastic ligature. This he encircled with catgut stitches to produce adhesion of the surrounding surfaces. The ligature, by constricting and cutting the tissues, effected an opening between the two organs. One dog lived eight days, when an examination showed the existence of a communication between the gall-bladder and the gut. Four dogs died four, six, eleven, and fourteen days respectively after the operation. Still, in every instance an opening into the duodenum was found. Twice the ligature had passed into the intestine, once it was found in the gall-bladder, and once lying upon the duodenum. It was intended to ligate the cystic duct in the dog that survived, with the view of directing the discharge altogether through the artificial opening. This was found impracticable, however, by reason of abundant adhesions, which had been formed in consequence of the operation.

Dr. Gaston claims that, "a permanent obliteration of the communication of the gall-bladder with the intestine is incompatible with health, if not inconsistent with the continuance of life." He asks whether "there is any guarantee of final and complete recovery" after cholecystotomy has resulted in the external discharge of the bile. In fact, Dr. Gaston states that, if the operation of cholecystotomy is ever to be crowned with success it must be resorted to while the patient has yet strength to outlive the depreciation of all the vital functions incident to an interruption of the supply of bile.

This extreme opinion implies an exaggerated notion of the importance of the gall-bladder to the economy. It is, moreover, not borne out by actual experience. It should be remembered that the physiological dignity of the gall-bladder is a rather low one. For it acts chiefly as a temporary receptacle for surplus hepatic secretion.

Now it has been repeatedly shown that, even in those cases in which no bile enters the intestine, and the stools remain clay-colored for a long time, the patients experience no serious disturbances.

Tait says that none of his cases suffered in any way, even when all the secretion has come through the fistula. Indeed, at times great improvement in health and in weight have been noted. Nor should it be forgotten that the gall-bladder has been entirely removed, and one-half of the cases operated upon have recovered, and, so far as known, remained well.

To perform Wells' operation, as Gaston suggests, and supplement it by uniting the bladder with the intestines,

would necessarily entail great danger. The external wound would either have to be kept open or reopened after closure. Adhesions would doubtless interfere with the success of the subsequent operation, as well in the human being as in the case of the dog, upon which Dr. Gaston attempted it. But apart from any considerations of a theoretical nature, the actual success that has so far attended cholecystotomy should be a sufficient guarantee that final and complete recovery after this operation may and does take place.

Improvements will doubtless be made in the surgery of the gall-bladder, but for the majority of cases it does not appear that the operation proposed by Dr. Gaston offers advantages sufficient to compensate for the additional risk its performance would entail. In the present state of our knowledge cholecystotomy, as performed by Sims and Tait, still offers the best possible chances of success. At the same time the fact should not be lost sight of, that before an operation is attempted at all, a positive diagnosis and accurate indications must be definitely established.

THE PATHOGENESIS OF SIMPLE ULCER OF THE STOMACH.

The mode of origin of simple gastric ulcer, in spite of much experimental study and careful clinical observation, is still involved in obscurity. That it should have claimed in almost equal degree the attention both of pathologists and clinicians, is by no means surprising, for it is not alone a theoretical interest which attaches to the subject. Evidently, if the causation and pathogenesis of the disease are more clearly understood, treatment, both curative and prophylactic, can be made more uniform, rational, and successful.

We have had occasion, from time to time, to allude to new investigations bearing on the subject (see Medical Record, September 22, 1883, page 321, and September 6, 1884, page 270), and to-day we wish to call attention to the most recent contribution relating thereto.

Dr. Stiénon (*Bulletin de l'Academie Royale de Médecine de Belgique*, vol. xviii., 1884) has just completed an elaborate study of the pathology of gastric ulcer. His researches were prosecuted at the histological laboratory of the University of Brussels. As the result of his labors he arrives at a certain number of conclusions that it may be worth while to examine. In the first place he shows that in order to obtain a proper understanding of ulcer of the stomach, and more particularly of its pathogenesis, it will be necessary to take into account not only those causes which originally produce it, but also certain influences that promote its tendency to become chronic.

The former do not lead to true ulceration, but only result in the formation of a simple wound with a tendency to cicatrization. The latter depend upon secondary tissue-changes, starting at the edges of the ulcer. Among such changes the author mentions destructive inflammatory action, cirrhosis, and excessive glandular development.

As regards the latter, he finds that it is a process in all respects similar to what is observed in certain ulcerations of the cervix uteri. Glandular hypergenesis of this kind may lead to changes which result in naked-eye appearances hardly distinguishable from cancer or epithelioma. Of course, a microscopical examination would remove any previous obscurity or doubt as to the true nature of the metamorphosis in question. But, long before the microscope would finally decide the matter, clinical observation should have made diagnosis possible. Yet Dr. Stiénon has nothing new to offer touching the symptomatology of gastric ulcer and its differential diagnosis from incipient cancer, or those perplexing disturbances of neuropathic origin that may seem at one time almost nothing, and at another may so closely simulate the gravest forms of structural disease of the stomach as to mislead the most experienced among us.

Glandular hypergenesis is also invoked by Stiénon to explain the phagedenic character of some chronic ulcers of the stomach. It is possible, however, for the destructive process to be arrested at any moment. In that case the glandular cavities become contracted under the surrounding pressure of new-formed cicatricial tissue. The development of the latter takes its origin from the connective tissue that is found beyond the epithelium of the gastric tubules. But this very epithelium becomes disintegrated and finally disappears completely, leaving only the cicatricial tissue already mentioned. Inflammatory irritation of the glandular epithelium may thus be the first step toward the formation of a true gastric ulcer of the chronic variety. But besides all this there lurks in all such epithelial irritation the added danger of cancerous metamorphosis. Epithelioma or true cancer is but the irregular or atypical glandular hypergenesis that ordinarily leads to ulceration. The secondary process of destructive degeneration is similar in both morbid conditions.

Whether we accept the views of the Belgian writer or not, it seems pretty clear that gastric ulcer and cancer of the stomach are pathologically more nearly related than is generally supposed. And from this point of view gastric ulcer acquires a new and graver importance than is commonly accorded it. This practical inference seems eminently justifiable, that convalescents from ulcer of the stomach should be strictly enjoined to avoid carefully any and every kind of gastric irritation; for a process of benign cicatrization may, under such irritation, become transformed into one of destructive malignancy.

THE CAUSES AND PREVENTION OF DENTAL CARIES.

Dr. Henry Sewill has written for the *Lancet* an article in which he sums up the causes and means of prevention of caries of the teeth. Caries is a process of disintegration, invariably commencing at the surface, proceeding inward, and due entirely to external agents; enamel and dentine are passive under this process. The predisposing causes of caries are: first, innate structural defects in the teeth, which render them more susceptible to the action of agents; secondly, all such diseases as are attended with vitiation of the oral secretions, or which tend to the formation and deposit of acid and the accumulation of products of decomposition within the mouth; thirdly, to crowding and irregularity of the teeth, due to smallness and malformation of the maxillæ. The direct agents in initiating caries are acids, the products of chemical change and fermentation set up in fragments of organic matter which are commonly present in the

mouth and lodge between the teeth. These acids are often assisted in their action by acid mucus secreted by unhealthy gums, acid saliva in some diseases, acid eructations from the stomach in others.

Enamel, according to Dr. Sewill, is always the starting-point of caries. The enamel organ—that portion of a developing tooth from which enamel is formed—consists of epithelial cells, and it retains its epithelial character throughout the process of calcification. The completed tissue results from direct calcification of the internal layer of cells. Vascular papillæ arise from the contiguous layer of the dental sac, penetrate to a slight depth the external layer of cells, and convey nutriment to the developing tissue. On completion of the enamel these external cells, with the vascular loops, undergo atrophy and disappear.

Dentine consists of a homogeneous calcareous matrix with a basis of fibrous tissue. It is permeated by minute tubes occupied by fibrils which endow the tissue with sensibility, and which form the sole protoplasmic element in dentine. The bearing of these anatomical and physiological considerations upon the subject of caries depends upon the obvious fact that enamel is devoid of any physiological mechanism whereby either vital or pathological changes could be brought about in it, and that whatever changes enamel undergoes are induced by external agencies. It is a calcareous mass, devoid of cellular elements, and incapable of imbibition. The one dark spot in our knowledge of the remote causation of caries, according to Sewill, is found in the first predisposing cause: inherent structural weakness of the tissues. The enamel varies indefinitely, in different individuals, in the quality of its calcareous matrix; we often, in fact, encounter teeth whose soundest enamel is chalk-like in its softness. Teeth of general defective character often present patches of surface, the enamel of which consists merely of an imperfectly united mass of granules. Sometimes, in places, enamel fibres are penetrated at their centres by minute tubes which render the tissue at such places porous. Honeycombed teeth have enamel full of small pits and fissures, and there is scarcely a set of teeth to be found in which here and there, in one or more teeth, an isolated crack or cleft, a solution of continuity of the tissue, does not exist.

While our knowledge of origination of mal-development of teeth is very incomplete, there is evidence that in all races of advanced civilization there is a notable deterioration in dental development. Comparative disease of the organs of mastication has led in civilized races to decrease in size and strength of the whole apparatus of mastication—jaws, muscles, and teeth. This fact has been demonstrated by Professor Flower, who shows by examination and measurement of many thousand skulls that there is a gradual diminution in the size of the teeth from the anthropoid apes through the lower races of man to the European. It has been argued that progressive dental deterioration may be brought about by the overwhelming demand upon the vital powers by the growth of the brain and its increased exercise in modern life. The brain and the jaws are alike fed from the common carotid artery, and it is urged that the demand for blood by the growing and working brain leads to imperfect supply of the masticatory organs. Again, dental deterioration has been ascribed to improper and imperfect feeding of children, to insufficiency in the food of lime salts, the proper pabulum of developing teeth. If this were true the whole osseus system might be expected to be ill-developed, and it would be impossible to find a single individual with a solid skeleton. Perhaps, with very rare exceptions, there is no modern people displaying general progressive physical degeneration, and which is accompanied by ill-developed teeth. But it must be recollected that there has been among the populations a constant augmentation in the number of the physically imperfect. Vast numbers of the phthisical, the scrofulous, the rickety, and the congenitally syphilitic who would formerly have perished in childhood, are now by science kept alive, and these imperfect types are all associated with faulty dental development.

With regard to the association of defective dental tissues with particular diatheses, we find ourselves on firmer ground. Hereditary syphilis leads often to the imperfect formation of tooth tissues. The children of syphilitic parents are apt to have the enamel soft and easily broken down.

Imperfect dental development is also found in the majority of cases of scrofula. One class of patients, the subject of phthisis of tubercular origin, almost invariably presents faulty dental tissues. This is the type most frequently found in females, in which there is often, with a fragile form, considerable facial beauty, in which the eyes are large and expressive, the complexion fair, with the blue veins visible beneath the skin. In this not uncommon type Dr. Sewill has invariably found the teeth, though well shaped and fair to look at, covered with the softest enamel. With rickets, too, inherently defective teeth are invariably found.

Premising that but little can be done to prevent dental deterioration, except by the promotion of national sanitation in the broadest sense, and that any treatment designed to influence beneficially the developing teeth of the fœtus in utero when the parents have been subjects of the diatheses or cachexiæ above mentioned can be of little effect, the writer considers other factors in the causation of caries, viz., vitiation of the buccal secretions. The diseases of our times are largely those which give rise to derangement of these secretions, for many or most of them are either diseases of the digestive organs or maladies accompanied by disturbance of the organs of digestion. In this way we may account for the prevalence of caries among certain portions of the community whose dental tissues are not of the worst structure. The constant presence of dyspeptic troubles in some classes of factory operatives is undoubtedly enough to account for the rapid tooth decay from which they suffer. Moreover, some of the diatheses, notably a variety of scrofula attended with a chronic condition of congested oral mucous membrane, and rickets, are often accompanied by a secretion of viscid saliva and acid dyspepsia. The broad facts now before us are: first, that without acid, without vitiation of the secretions of the mouth, caries is impossible; and, secondly, that acid capable of dissolving enamel—and of more rapidly dissolving it in proportion as the tissue is soft and ill-made—is always being formed in greater or less quantity in every mouth in which absolute cleanliness does not exist.

In combating this second cause of caries, the patient's general health must first be considered, and we must remember that probably every lapse from a perfect standard will be attended with a proportionate vitiation of the secretions of the mouth. The question of the general health should then first receive attention and dyspeptic troubles be remedied. But even with perfect health and perfect dental tissues caries may appear if organic débris be allowed to remain and decompose in contact with the teeth. The first thing, therefore, in every case is to insure mechanical cleanliness by the use of a tooth-brush and tooth-pick, which latter should be of quill or wood only. When the teeth are crowded and of delicate structure, the use of floss silk passed between the teeth and rubbed to and fro supersedes the use of the tooth-pick. The tooth powder recommended by Dr. Sewill is as follows: Take of Castile soap, two drachms; powdered orris-root, half an ounce; borax, two drachms; and prepared chalk, two ounces. Mix and rub together; flavor with a few drops of oil of cloves and lavender. Instead of the perfume, Dr. Sewill has lately added a few drops of carbolic acid to each ounce of the powder, the whole being flavored with eucalyptus oil. The mixture should be used freely with a wet tooth-brush, the mouth to be freely rinsed with water at intervals during the brushing. In all cases where great vitiation of the secretions is present, as in the dyscrasia of pregnancy, extra means should be adopted to prevent putrefaction and fermentation in the deposits which form upon the teeth. A useful mixture for this purpose is made by dissolving a grain of bichloride of mercury in an ounce of eau de Cologne or tincture of lemon. Mix a teaspoonful of this with two-thirds of a wineglassfull of water, and rinse the mouth with it several times a day.

As for the caries which depends on crowded jaws and irregularity of the teeth (favoring retention of food-débris in contact with the teeth), the most beneficial measure to prevent caries in these cases, especially when the teeth are of imperfect formation, is the extraction of the six-year-old molars as soon as the second molars are well in place. The first permanent molars are generally the worst-made teeth of the set, and in cases where room is urgently needed it is seldom that their permanent preservation is possible. Removal of these teeth allows an equal and sufficient spreading apart of all the teeth and prevents the evils of crowding. The operation of filing and polishing the contiguous surfaces of canines and incisors as an effectual means of cutting short the progress of incipient caries in crowded jaws is too well recognized to need comment.

THE DOCTOR AND RELIGION.

If to serve one's fellow-man be the essence and the end of religion, no one is more devout than the doctor. If, as most think, and we among them, religion includes also something spiritual, a duty to God, a reverence for things eternal, a faith in the unseen and undemonstrable, then doctors are, many of them, lacking. Every profession has something in it which tends to drag the man down from higher planes. The clergyman is in danger of losing manliness and liberality of thought; the lawyer, a fine perception of the absolute value of right and wrong; the doctor, his faith. The doctor sees so many promises fail, hears so much that turns out false, reads so much that proves to be rubbish, that as he passes on in life he becomes more and more inclined to base his convictions only on that he has himself seen or known. What wonder that he sometimes doubts the beneficence of misery, and the utility of piety, or questions if the human wrecks that he meets have been ennobled with immortality, or stamped in the image of God.

While we trust that the spirit of benevolence and kindness is not growing any the less among the profession, there is a probability that reverence and faith are being supplanted, in a measure, by indifference and agnosticism. This is in accordance with a tendency, we will not say of the age, but of the period. If it is a fact, it should excite deep regret and call for earnest protest. We do not propose to preach a sermon, but we say with all the emphasis in our power, that the doctor should avoid this tendency and cultivate the feelings of reverence and faith. Mr. Jonathan Hutchinson, in one of his addresses to medical students, once said that faith was the most essential element of success. Taken in its largest meaning, nothing is more true, and nothing is more worthy of being impressed upon the young physician's mind. It is this which gives earnestness to purpose, sincerity to character, and a hope and object in living. Agnosticism is a cancer which eats into the moral fibre, deadens the higher impulses, and takes away half the joy of living and half the chances of a successful and useful life. We say, then: let the physician think what he pleases, but let him believe and hope, leading withal a reverent and truthful life.

LEADING THE WORLD IN MEDICAL JOURNALISTIC ENTERPRISE.

Dr. Edward Bork, of St. Louis, has written an interesting and instructive account of his last summer's experience abroad. Alluding to the International Medical Congress, at Copenhagen, he says: "The New York Medical Record was the only medical journal that had a shorthand reporter present at the Congress, and all speeches and proceedings were cabled at once across the Atlantic (see Medical Record, August 16, 1884, and following numbers). The reporter, of course, had some difficulty in obtaining the reports of the secretaries of the different sections, as it was impossible for him to be present at all of them at the same time. But the slowness of rendering assistance to the reporter by the secretaries, I feel sure, was not through lack of courtesy or willingness on their part to do so, but it depended more upon the non-understanding nor apprehension of our ways and methods of doing business quickly. They are slow in all their ways in the old country. Nevertheless The Medical Record deserves great credit, which should be liberally acknowledged by the medical profession."

As all the leading medical journals, both in this country and in Europe were represented at Copenhagen, we can justly claim that in the thorough efficiency of our reporter, in the promptness and completeness of his work, and in the pecuniary outlay made for the benefit of its readers, The Medical Record took the lead.

A NEW WORD.

When medical science contributes a new word to the vernacular, it is a matter of sufficient importance to deserve comment. The newspapers and periodicals during the past summer very soon got hold of the word "microbe," and it has already become considerably popularized, being much more generally used than the word "bacillus." Recently a Chicago drummer, in the heat of argument, called a St. Louis fish-merchant a "leather-faced, crop-eared, malaria-ridden microbe." This characterization has been promptly and extensively taken up by the press of the West. The fate of the word is settled, and microbe is now a part of the English language. A too-learned medical contemporary has given currency to a popular mistake regarding the origin of this word, attributing it to Sédillot.

The word macrobe, which means long-lived, has been employed for centuries. Pomponius Mela, a Roman geographer, applied it to a race of long-lived Ethiopians, and Rabelais gave the name *Macrobio* to one of his characters.

The word microbe should mean, by contrast, short-lived, but it may very well mean "small life" also, and such is the significance given it by Filippo Pacini, of Florence, who in the *Gazetta Medica Italiana*, thirty years ago, described a small organism which he called "microbio colerigeno." Whether Sédillot devised the word independently in 1878, as is probable, or whether he had see Pacini's communications, we cannot say. At any rate, it is only since the Frenchman's adoption of it that it came into any general use.

The *Medical Annals* discusses the question of pronunciation, and thinks that it should be divided in three syllables, mi-cro-be. This is a mistake, however. The word is given us by the French, who make but two syllables, while the three-syllable word, mi-cro-bie, is left, at Littre's suggestion, to indicate a state or condition.

THE REQUIREMENTS OF ADMISSION INTO THE MEDICAL CORPS OF THE ARMY AND OF THE NAVY.

A brief note which we made some weeks ago regarding vacancies in the medical corps of the army and navy, has caused us to be flooded with inquiries from all quarters. Our correspondents wish to know how many vacancies exist at present in these departments, and what are the requirements for appointment.

Since our last writing, the report of the Surgeon-General of the Army has appeared, in which it is stated that the fourteen vacancies existing the year previous have now all been filled. The Surgeon-General informs us that there are now no vacancies in the Army Medical Department, but that there probably will be such before long, and that an Examining Board will be convened in the Spring.

For the convenience of those desiring to prepare themselves for examinations before such Board we append some of the regulations governing it:

"All candidates for appointment in the Medical Corps must apply to the Secretary of War for an invitation to appear before the Army Medical Board of Examiners. The application must be in the handwriting of the applicant, must state date and place of his birth, and place and State of which he is a permanent resident, and must be accompanied by certificates based on personal acquaintance from at least two persons of repute as to citizenship, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age (without any exceptions), and a graduate of a regular medical college, evidence of which, his diploma, must be submitted to the Board."

"The morals, habits, physical and mental qualifications, and general aptitude for the service, of each candidate, will be subjects for careful investigation by the Board, and a favorable report will not be made in any case in which there is a reasonable doubt."

The physical examination is very rigid.

"The Board will satisfy itself by an actual examination that the candidate possesses a thorough knowledge of the branches taught in the common schools, especially of *English Grammar, Arithmetic, and History and Geography of the United States.*"

"An examination on general science will include Chemistry and Natural Philosophy; and that on general literature will embrace English literature, Latin, and general history, ancient and modern. Candidates claiming proficiency in other branches of knowledge, such as the higher mathematics, the ancient and modern languages, etc., will be examined therein and receive due credit therefor."

"Written examination on anatomy, physiology, surgery, practice of medicine, and general pathology, obstetrics, and diseases of women and children. Oral examination on these subjects, and also on medical jurisprudence, materia medica, therapeutics, pharmacy, toxicology, and hygiene. Few candidates pay the attention to hygiene which it deserves."

"Clinical examination, medical and surgical, at a hospital."

"Performance of surgical operations on the cadaver."

"Due credit will be given for hospital training and practical experience in surgery, practice of medicine, and obstetrics."

The requirements and examinations for the Navy are of about the same character as those for the Army. Those desiring particular information should write directly to the Surgeon-General.

News of the Week.

Professor Virchow has had a severe attack of the gout. The great pathologist took a course of Carlsbad waters and was cured by them—and time.

A Statue of Professor Bouillard, of Paris, is being made by the sculptor, M. Vernet.

During 1884, the Six Faculties of France produced about seven hundred doctors.

An American Society of Public Analysts was organized in Brooklyn on the 24th of last month, by representatives holding appointments under the Boards of Health in the several States of the Union. Its objects will be, by frequent meetings, the discussion and publication of papers, etc., to advance and disseminate knowledge regarding adulteration of food or drugs, to secure uniformity of results, and to provide for efficient sanitary control over the food-supply. A meeting was held December 8th for the election of officers.

Characteristics of the Cholera Epidemic of 1884.—These, as summed up by a committee of the Académie de Médecine, composed of M.M. Dujardin-Beaumetz, Hardy, and Proust, are as follows: 1. Relative benignity, corresponding with the regular decrease in the gravity of cholera epidemics since 1832. 2. Absence of special premonitory constitution, as shown by choleriform diarrhœas. 3. Uncertainty, or at least great variability, in the mode of propagation. 4. Many facts showing that the disease is very contagious; many others showing the contrary.

The Trial and Acquittal of Dr. Fordyce Barker by the New York Academy of Medicine.—The trial last week of Dr. Fordyce Barker before the New York Academy of Medicine, of which he was President, for improperly claiming a Paris degree of Doctor in Medicine, was a sad business. We care very little for the evidence in the matter one way or the other. But the forcing of such an issue, in such a manner, against a professional brother of Dr. Barker's standing, bears too plainly the impress of personal pique and spite. The profession of medicine can gain nothing from such performances. This trial is to be regarded as a melancholy echo of the wrangle over the Code in New York last year. Whatever opinion we may entertain of the wisdom of the men who forced that foolish issue last year, we are glad to be able to congratulate Dr. Barker heartily upon the handsome vindication he has received.—*Boston Medical and Surgical Journal.*

An Official Register of Physicians and Midwives of Illinois has been issued by the Board of Health of that State.

The City Physicians of Atlanta, Ga., receive a salary of eighty-five cents a day, and furnish their own medicine.

A Mode of Curing Cancer.—Dr. H. M. Lawson, of Cuthbert, Ga., who is described by the editor of the *Southern Medical Record* as "a modest though worthy practitioner," announces a cure for cancer. It consists, as we understand, in the heroic use of arsenic combined later with caustic applications. In one patient suffering from epithelioma on the left temple, one-fourth of a grain of arsenious acid was given, and gradually increased to three-fourths of a grain.

A Reply to Koch.—Professor Winckler, who claimed to have discovered true comma-bacilli of cholera in cholera nostras, has written an elaborate reply to Koch in the *Gazette de Cologne.* He denies that his methods of culture were faulty and reaffirms his original opinion, viz., that the comma-bacillus of Koch differs very little in form from that of cholera nostras, and that the differential points laid down by Koch are not sufficient for diagnostic purposes.

Death of Dr. George H. Atkinson.—The death of Dr. Atkinson, of Brooklyn, was one of the saddest illustrations of the physical dangers of a surgeon's life. Dr. Atkinson died from a painful and distressing disease contracted in the discharge of his professional duty. Last August, while operating, as we are informed, the patient, who was suffering from syphilis, became irritable under the knife and scratched the middle finger of the doctor's right hand with his nails, breaking the skin and drawing blood. The wound was small, but the doctor took proper precautions and gave the matter little further thought. A week or two afterward the finger, and subsequently the hand and wrist, began to swell. Dr. Atkinson knew his danger, and began a prompt course of treatment with mercury. Toward the end of November, he began to feel pains in his head and limbs, attended with constant drowsiness. It was with difficulty that he could attend to his patients. About a week ago, while sitting in his office, he was seized with partial paralysis. The next morning he was unconscious, and he then grew steadily worse. During brief intervals of consciousness he has been able to express his wants by signals, but he could not speak an intelligible word. He died last week, a victim of malignant syphilis.

Dr. Atkinson was born at Portland, Or., in 1851, and was graduated from Dartmouth College in the Class of '71. He came to Brooklyn the same year, and having studied medicine at Dartmouth, he was graduated the following year from Long Island College Hospital. After his graduation he was appointed assistant surgeon in the hospital, and two years ago he was appointed full surgeon. At the time of his death he was a lecturer on surgery and genital diseases in the collegiate department of the institution.

Dr. Atkinson was a man of fine physique, and was personally very popular among his associates.

The late Dr. William Darling.—At a meeting of the Faculty of the Medical Department of the University of the City of New York, held December 26, 1884, the following resolutions were adopted:

Whereas, At the end of a long life, devoted to the profession of which he was a learned and honored member, William Darling, A.M., M.D., LL.D., F.R.C.S., has been removed from our midst; and

Whereas, It becomes those who have been associated with him as colleagues for many years, to give official expression to their sense of the loss they have sustained in his death. Be it therefore

Resolved, That we, the members of the Faculty, fully appreciating his great learning, his wonderful ability as a medical teacher, and believing that the most enduring monument to his memory will be found in the record of his life, here tender to his relatives and friends our heartfelt sympathy in their grief.

Resolved, That these resolutions be spread upon the minutes of the Faculty, and be published in the medical journals of this city.

J. W. Wright, M.D.,
W. M. Polk, M.D.,
Committee.

New York Academy of Medicine.—This Society, as is known, has its handsome building centrally situated at 12 West Thirty-first Street. Its large and valuable library, with its extensive circulating department of the medical journals of both hemispheres, is specially attractive and useful. The Society is doing good service to science, and the papers read before the Association, and the discussions thereon, constantly appear in these pages. The library has been made a public one, and the laity and profession can consult it daily without cost, Sundays and

holidays excepted, until 9 P.M. A mortgage of $5,000 remains on the premises, and it has recently been proposed to liquidate this, so that it can commence the new year free of this incubus. The Society needs all its available income to promote its scientific objects. Already between two and three thousand dollars have either been paid or subscribed for the purpose, and it is hoped every Fellow will aid in this desirable work. Any member of the Committee of Ways and Means is authorized to receive subscriptions. Committee—Dr. Gouverneur M. Smith, Chairman; Dr. Fred. A. Castle, Secretary; Dr. Willard Parker, Treasurer; Drs. C. R. Agnew, A. Jacobi, A. A. Smith, V. P. Gibney, Wesley Carpenter, P. A. Morrow, E. D. Hudson, C. C. Lee, H. L. Hanks, Everett Herrick, A. M. Jacobus.

THE NEW HEALTH BILL.—Dr. A. L. Carroll, of New Brighton, N. Y., writes: "The bill proposed by the conference of State Boards of Health, to establish a National Board of Health, appears to need much revision before it can justify your semi-laudatory comments, or give promise of an efficient, or even tolerable, organization. In the first place, the provision that the President's appointment of members must be "confirmed by the Senate," affords a possibility, if not a probability, that political rather than sanitary qualifications might be considered in the selection of representatives of the several State Boards; and in the second place, in the absence of any specified tenure of office, these members are seemingly to be appointed for life, to hold annual (and intermediate) meetings at Washington until death or future Congressional action shall part them from the potential profits of the proposed machinery. No qualifications are predicated for the Secretary (the mode of whose appointment is not mentioned), who can only be removed by a two-thirds vote of the full Board; so that, for all that the proposed bill says to the contrary, we might have a National Sanitary Board without a single sanitarian upon it; its business conducted by an executive officer wholly uneducated in aught that relates to epidemiology or preventive medicine, drawing any part of an annual half-million dollars which the Board at its first meeting may choose to award him, and clinging to his position as long as a minority consent to his retaining it. The only nominal control to be exercised over his action is by means of an executive committee of seven, "representing the various geographical divisions of the country," none of whom are required to possess any knowledge of the rudiments of hygiene. And such a possibly incompetent body is to be empowered to make rules and regulations in its discretion to control commerce in foreign ports as well as at home, and to dispense a tempting amount of "patronage." I do not, of course, mean to intimate that, even in such a cumbrous machinery as that which is proposed by the bill in question, it would not be possible to congregate from the various State Boards of Health (if the boards themselves had the power of selection) a representative body of sanitarians whose opinions might not irreconcilably clash on subjects connected with "the control and protection of the public health of the United States;" but better guaranty should be demanded of the "selection of the fittest" before the medical profession or the mercantile community endorse a measure giving permanent and arbitrary powers to an irresponsible central board. It is proper to add that the printed copy of the proposed bill, issued by the conference for Congressional action, contains provisions for enforcing the rules of the National Board within the States by persons to be appointed by the President for that purpose, which provisions are omitted from the draft published in your columns."

[The bill, as sent to us, was understood to be the amended one presented to Congress. It was so stated to be by the Committee having it in charge.—ED.]

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY.—At the annual meeting of the Northwestern Medical and Surgical Society, the following officers were elected for the ensuing year: *President*—Dr. Thomas H. Burchard; *Vice-President*—Dr. A. R. Robinson; *Secretary and Treasurer*—Dr. J. Henry Fruitnight; and *Committee on Admissions*—Dr. S. Barnet, Dr. E. S. Peck, and Dr. Charles A. Leale.

THE LATE DR. A. S. CHURCH.—At the last regular meeting of the Northwestern Medical and Surgical Society, the following resolution was adopted:

Resolved, That in the death of Dr. A. S. Church, this Society has met with a great loss, which we all most deeply deplore; that his kindly, genial smile, accompanied by his always welcome presence will be missed by us, and that we can only in this sad bereavement tender to the family of the deceased our heartfelt sympathy.

CHARLES S. WOOD, M.D.
CHARLES A. LEALE, M.D.
MARK BLUMENTHAL, M.D.
Committee.

A DISPENSARY WHICH PAYS ITS MEDICAL ATTENDANTS.—It is reported that the New York Dispensary is to be reorganized. All the present staff, save the House and Assistant-House physicians, will resign, and a new one appointed after a competitive examination of candidates. The successful physicians will receive $800 a year, for which they will be required to contribute four hours of their time daily.

SURGEON P. H. BAILHACHE, of the Marine Hospital Service, known in this city from his connection with the Service here a few years ago, has been assigned to duty in Philadelphia.

PROPOSED STATE BOARD OF MEDICAL EXAMINERS AND LICENSERS IN PENNSYLVANIA.—A bill has been prepared for presentation before the Legislature of Pennsylvania during the present winter, having for its object the establishment of a permanent commission, to be known as the State Board of Medical Examiners and Licensers, which shall have the power to pass upon the qualifications of all physicians seeking to practise medicine or surgery in the State of Pennsylvania after September 1, 1886. The bill has been framed with care by a Committee of Conference consisting of members of the Philadelphia Medical Jurisprudence Society, members of the Philadelphia County Medical Society, and Pennsylvania State Medical Society, as well as from the Homœopathic State Medical Society of Pennsylvania. It will only affect those who enter upon practice after September 1, 1886. It is thought that it cannot affect graduates of Pennsylvania institutions. The sentiment of the medical press seems to be in favor of the bill.

Obituary.

PROF. WILLIAM DARLING., A.M., MD., LL.D., F.R.C.S.,

NEW YORK.

It is our painful duty to announce the death of Professor William Darling, the distinguished anatomist, which occurred on Christmas morning. The deceased was not alone noted as one of the most accurate anatomists and an excellent mathematical and classical scholar, but was remarkable for a strong individuality, regarded by many as approaching the realm of eccentricity, which served to render him one of the best-known figures in the medical community. He descended from an old Scotch family, Grace Darling, the well-known heroine, being a cousin by blood of the Professor. He was born in the old town of Dunse, the one from which the celebrated scholar, John Duns Scotus, derived his middle name. It was among his peculiarities that he was very reticent as to his age and relatives; to an intimate friend he admitted that he was born in 1805, while a biographical notice gives 1815 as the figure; the death certificate, however, as well as the funeral notice, assign eighty-two years as his age, and this figure is evidently near the truth. After receiving a good preliminary education, which began at the University of Edinburgh, he came to this country in the early part of the century with his father, who had failed in business in consequence of the depressed condition of trade. The date of his advent is not accurately known, but may be fixed from the fact that he had already been in this country several years when Captain Marryat made his American tour. At first Professor Darling had a severe struggle with adverse circumstances, and obtained subsistence by acting as a private tutor. Among the families in which he served in this capacity was that of Doctor Valentine Mott, and to the interest which the latter took in the young man, his subsequent choice of the medical profession and adoption of the teaching career is due. He entered the University and studied for a much longer period than was necessary, being of unusual diffidence and bashfulness. The deceased Dr. Benjamin Raphael, who knew Dr. Darling then, frequently spoke of him as having at this time developed those characteristics for which he became noted later on. He graduated at the school in which he subsequently became a teacher, in 1842, and continued private instruction in anatomy, which he had begun while an undergraduate. He made many of Dr. Mott's dissections, and was his prosector for some years. Then he occupied at various times the position of physician to the Quarantine Hospital, Sailors' Snug Harbor, and the Emigrant Asylum. It was while on Staten Island that he laid the foundation for the collection of dried anatomical specimens, which to this day is the largest and best selected accumulated by a single man. The grave-yards and charnel-houses furnished at that time a rich mine for the collector; many Indian and negro skulls were unearthed by him, and among the most prized treasures was a skull with an enormous interparietal bone, which, it is believed, cannot be duplicated in any European collection.

Having through his rigid economy accumulated sufficient funds, he carried out a long-cherished wish and went to England, where he entered at the Royal College of Surgeons, and studied under Owen, Huxley, and other distinguished anatomists, until he regarded himself proficient. In after years the writer was told by one of his contemporaries, at the time an officer of that institution, that when the uncouth candidate appeared before the examining board, the latter were inclined to treat him with *hauteur*, and expected a lamentable failure. So thoroughly grounded was the candidate, however, that in a few minutes, as one of the examiners remarked, the tables were turned, and the candidate seemed to be examining his examiners. He passed with flying colors, and took the degree of Member in 1856, and after the necessary interval of ten years more, that of Fellow of the Royal College of Surgeons, being at the time of his death the only one in the United States. In 1866 he had resumed his position as demonstrator of anatomy, and having filled the vacancy caused by the death of Professor Pattison to the greatest satisfaction of the Faculty and students, was in that year appointed Professor of Anatomy at the Medical Department of the University of the City of New York. He was an earnest teacher, and his devotion to the subject such that, with other of the distinguished teachers of the past who identified themselves with their subject, he was familiarly known by an osteological cognomen. At the same time he was respected, loved, and admired, as teachers of more glittering qualities have not been. The secret of his influence lay in the essential worth of the man, and if he was a popular figure with those who graduated under him, it was more due to this than to those peculiarities which enhanced his value at the social board with his confrères. Endowed with a prodigious memory, and master of the classics, he was able to carry the burden of entertainment single-handed during an entire evening. His memory of dates, names, and events in local medical history would have enabled him to have written a chronicle of interesting and important events which, it is feared, cannot be furnished by any one now living. He was in this respect a link between the first and last halves of the century. His early reminiscences were of the period of Mott, Cheesman, and Pattison, while his memory remained green to his dying day for recent as well as ancient events, and he was as capable of assimilating and reproducing an anatomical subject toward the close of his life as he was accurate in reproducing from memory whole pages of the ancient and modern classic authors.

Professor Darling lived as a bachelor, having rooms at the University building. He regularly left the College at three o'clock every afternoon, and walked on foot to and from Rolfe's chop-house in John Street, where he dined. He was singularly robust, and careless with regard to the vicissitudes of the weather. His resistance to the latter engendered an over-confidence, which undoubtedly led to his fatal illness. On the Wednesday preceding Christmas week he was last seen in a well condition. From this day to the Monday following little is known of him. It transpired, however, that he went out on a cold Thursday (December 18th) inefficiently clad, and was seen tottering along Broadway on Friday, evidently in a delirious state. In this condition the old gentleman fell, probably several times, producing three abrasions of the scalp. His further history is a blank till Monday; he seems to have lain in his room, without food or medical attendance. On that day Doctor Polk saw him and prescribed for the patient, whose peculiarities rendered him as reticent regarding his suffering as he was in other respects. He wrote Dr. Spitzka, who found him in a typhoid state that evening, and suffering from a pulmonary disorder. He continued, with the sanction of Dr. Polk, under his treatment and that of Dr. Brill, who the following morning determined the existence of croupous pneumonia of the upper part of the right lung, with general bronchitis. There was a slight rally during Tuesday and the night from Tuesday to Wednesday, when the patient became entirely lucid. He declared that he expected to recover, and declined to have any relatives or friends notified of his illness. Many of the latter called, but the patient was becoming so feeble that only those whom he expressed a special wish to see could be admitted. On Wednesday evening he was last seen by Dr. Brill, who found him hopelessly sinking and becoming unconscious. He died at a few minutes after four o'clock, having delivered in his terminal delirium a coherent anatomical disquisition. Among the last subjects regarding which he spoke while in a lucid condition was the disturbance in the Academy of Medicine

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 26, 1884.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. T. MITCHELL PRUDDEN presented, in behalf of a candidate, a specimen of *chronic endarteritis*, with obliteration of the left subclavian artery.

REMOVAL OF THE COCCYX.

DR. J. A. WYETH presented the coccyx removed from a male patient thirty-six years of age, and a native of South Carolina, who came to New York two years ago for surgical relief. The patient received a fall about four years ago, striking upon the buttock. No peculiar symptoms developed at the time, but afterward he suffered occasionally from spasms of the sphincter ani muscle. He was examined by a physician who said he detected a fissure of the anus, and operated upon the patient with the knife, but the disease was not relieved, and he was again operated upon for the same fissure by stretching.

Dr. Wyeth saw the patient about six weeks ago, and detected that the coccyx had been displaced forward, and was projecting directly upon the posterior wall of the rectum, so much so that when the finger was introduced he found a kidney-shaped passage, two and a half inches above the anus. In the meantime, the patient had become filled with the idea that his case was beyond help. Dr. Wyeth removed the coccyx, and for two or three weeks after the operation the patient was relieved, and Dr. Wyeth believed that recovery would ensue, although the patient was unwilling to admit that he was cured.

Dr. Wyeth also exhibited

A MODIFICATION OF DR. OTIS' URETHROTOME.

The modification consisted in the attachment of a cog-wheel arrangement, by means of which the movements of the knife could be regulated and arrested at any desired point.

DR. PEABODY asked if any other member had met with cases where it seemed to be desirable to remove the coccyx, and in which the operation had been performed without giving relief. He referred to a case of coccygodynia in which the operation was performed without affording relief, and the patient was subsequently cured by anti-neuralgic remedies.

DR. GARRISH had met with several cases, and had performed the subcutaneous operation of division of the nerves, sweeping the knife around the coccyx close to the bone. He obtained the idea of this plan of treatment from the instruction of the older Dr. Meigs.

DR. WYETH was unable to understand how the nervous supply of the coccyx could be reached by such an incision, as it was exceedingly difficult to cut the coccygeal nerve upon the cadaver. Some of the superficial branches, however, might be divided by such subcutaneous section.

DR. W. M. CARPENTER referred to cases recently reported by Dr. Goodell, of Philadelphia, who had practised subcutaneous division of the tissues immediately surrounding the coccyx, but unsatisfactorily, and recommended that, in all cases of true coccygodynia, the coccyx be removed.

DR. L. EMMETT HOLT presented specimens illustrating

GANGRENE OF THE LUNG IN A CHILD, FOLLOWING PRIMARY PNEUMONIA—ACUTE PARENCHYMATOUS NEPHRITIS.

"A. M——, aged three years, came under my observation November 5, 1884. He was a well-developed boy and had been, up to the beginning of the present illness, apparently in perfect health. Had never had measles, scarlatina, diphtheria, nor any other sickness except one attack of 'bronchitis' two years before, lasting a few days only. He was taken quite suddenly, about noon of November 3d, with a high fever and some cough. Was very restless, constipated. Temperature, 104½°, pulse 200, when first seen. For a week he continued to have a high fever, his temperature ranging from 103° to 104½°, in spite of full doses of cinchonidia. The physical signs were: slight dulness over the lower half of the right chest, behind, which gradually increased in intensity; coarse and firm mucous râles over both lungs; high-pitched breathing over the right base, behind; splenic dulness slightly increased.

"At the end of a week his prostration became extreme, the face was very pale, sordes formed on the lips and teeth, the mouth bled easily, and he lost flesh rapidly. The pulse was frequent and feeble, while the respirations were not much accelerated, and the temperature dropped to 101°. He could be made to take but very little nourishment, and stimulants only in small quantities. The bowels were loose, the urine was passed freely, there was no vomiting, and no cerebral symptoms except a little drowsiness. The physical signs now became more pronounced; there was decided dulness over the lower half of the right chest, extending forward to the anterior axillary line. Over this part were heard pleuritic friction sounds, a few râles, and feeble distant bronchial and broncho-vesicular breathing. The rest of the chest showed only exaggerated resonance and fine râles. The heart's apex was not displaced. Subsequently the temperature again rose to 104° and over, and although he now took nourishment better and stimulants in quite large amounts, he sank steadily and died from pulmonary œdema, early on November 18th, after an illness of exactly two weeks. There was no expectoration, no fetor to the breath, no dropsy, and the urine was passed freely up to the day of death.

"*Autopsy*, made eight hours after death.—The *brain* was not examined. *Chest.*—A sacculated pleurisy was found occupying the lateral and posterior regions of the right chest, containing five or six ounces of dirty brownish serum. Both the lungs were pretty firmly adherent to the chest-wall throughout nearly their whole extent; the left was particularly adherent to the diaphragm. The heart was not displaced and the pericardium was normal. The *right lung* was covered with a thick false membrane, which could be torn off in large strips. It was of a yellowish color. The upper lobe crepitated on pressure, but rather less than normal, and on section showed marked congestion and moderate œdema, but no pneumonic changes to the naked eye. The lower half of the lung was solid, did not crepitate, and sank in water. The diaphragmatic surface presented two irregular patches of a dark gray color, with rounded borders distinctly circumscribed and softer than the surrounding tissue. From these larger patches a number of smaller ones branched off, both together embracing about one-half of this surface of the lung. On section these dark patches were found to correspond to gangrenous areas in the lower part of the lung. This part embraced about two-thirds of the lower lobe. It was separated by a tolerably defined, but very irregular line. It was made up of patches of necrosed lung tissue, gray at their borders and almost black at the centre. The largest were about the size of a walnut, the smallest of a small pea.

"The lung tissue was so disintegrated that it could be washed away by a current of water. Many of these patches touched each other and formed irregular masses, while about and between them on other sides were parts of lung tissue showing only hepatization. The pleura was not perforated at any point. There was no gangrenous odor. Careful dissection of the pulmonary artery showed no obstruction and no disease. The gangrene did not seem to follow the arterial distribution. It did correspond to the distribution of the bronchi. No change was found in these other than those of an intense catarrhal inflammation. About four-fifths of this region of the

lung was gangrenous. It presented a peculiar honeycombed appearance.

"The *left lung* was covered with a thin false membrane, not so tough as that of the right side. The gross appearances of the lung showed only the changes of bronchitis, congestion, and some œdema. The *bronchial glands* were not enlarged nor cheesy.

"The *heart* walls and valves were healthy; a post-mortem clot was found in the right ventricle. The *liver* was somewhat enlarged and slightly fatty. The *spleen* was about twice its normal size, and was firmer than normal. The *kidneys* were nearly as large as in the adult, a little softened, of a light yellowish color, capsule not adherent. On section the right showed swelling of the cortex, the markings being quite indistinct. The cortex was of a yellowish white color. The changes in the left were similar, but not quite so decided.

"The *bladder* contained about two ounces of urine. An examination of this yielded about five per cent. albumen; the microscope showed a large amount of epithelium from the pelvis of the kidney, from the kidney itself, and some from the bladder. Also numerous fragments of epithelial casts, a few hyaline casts, and some blood. The other viscera were healthy. There were no tubercles found anywhere."

Dr. W. P. Northrup made the following report concerning the *microscopical examination:* The lung exhibited the characteristics of gangrene. There was between the branching areas of gangrene ordinary broncho-pneumonia, the product of the inflammation being mostly pus with some swollen epithelial cells. These areas gradually merged into the areas of necrosis, and these in turn into the areas of gangrene, which consisted of a grumous soft mass of granular matter containing the bacteria of putrefaction. The pneumonia on the opposite side was the ordinary broncho-pneumonia. There was, probably, some parenchymatous change in the kidneys. He thought Dr. Holt was justified in saying that there was acute parenchymatous nephritis.

Dr. Prudden thought it was necessary, in this case, to take into consideration the possibility of gangrene being secondary to the pneumonia in a rather general way; that is, that the gangrenous areas might be due to hemorrhagic infarction. He thought that in considering the statistics on this subject, this form of gangrene should be separated from the diffuse variety which occurs not infrequently in pneumonia.

Dr. Northrup asked if there was anything peculiar in the fact that the areas of gangrene, in this case, seemed to follow the ramifications of the bronchi.

Dr. Holt remarked that Gerhardt, in his "Handbook on Diseases of Children," under the head of Gangrene, described almost exactly the case which he had presented, and stated that gangrene generally affects groups of lobules, and that the irregular scattered patches of gangrene are the form in which the disease occurs in children.

Dr. George L. Peabody then made the following remarks concerning

THE RELATION EXISTING BETWEEN RETENTION OF UREA AND URÆMIA.

"Mr. President, at the last meeting of this Society, reference was made to the investigations of Grehant and Quinquand on the subject of uræmic symptoms being produced by subcutaneous injection of urea in animals. Yesterday I took occasion to refer to their paper in the *Comptes Rendus* for August 25, 1884. These observers were able to produce convulsions, coma, and death in frogs, guinea-pigs, rabbits, pigeons, and dogs, by injecting subcutaneously enormous doses of urea. They give us the doses necessary to produce these results in these animals as follows: In the frog the urea was equal to $\frac{1}{3}$ of the weight of the animal; in the guinea-pig, $\frac{1}{8}$; in the rabbit, $\frac{1}{100}$; in the pigeon, $\frac{1}{35}$; in the dog, $\frac{1}{150}$.

"Now, taking the smallest amount with which they were able to produce these results, and transferring, for the sake of argument, the results to the human animal, we find that in order to produce uræmia artificially in a man weighing one hundred and fifty pounds, one and a half pound of urea would have to be injected subcutaneously.

"According to Hermann, in the human adult $\frac{1}{13}$ of the weight of the body is made of blood. In man the same author tells us that, in 1,000 parts of blood, 624 parts are plasma. The following calculation tells us simply, therefore, that the man weighing 150 pounds has 7.1999 + lbs. plasma:

$$150 \times \tfrac{1}{13} \times .624 = 7.1999 +$$

"For practical purposes, to simplify our calculation, let us consider the plasma of the man weighing 150 pounds equal to 7.20 pounds, and let us also consider, only for practical purposes, plasma and serum as equivalent terms. Hoppe-Segler and Oppler, working separately, each found in the blood of a uræmic patient 1.27 parts urea to the 1,000 parts serum.

"Now, sir, I believe that I am correct when I say that in the following proportion x will represent the total amount of urea in the serum of the uræmic man weighing 150 pounds:

$$1.27 : 1000 :: x : 7.20, \text{ or } x = \tfrac{9.14}{1000} \text{ lb.}$$

We are taught that urea is found in other fluids of the body and some of the tissues, but chiefly in minute proportions. Let us allow, for the sake of argument, that it is present throughout the entire body of the uræmic subject in the same proportion as it is in his serum. The following proportion will represent this idea:

$$1.27 : 1000 :: x : 150 —$$
$$x = .19 \text{ lb.}$$

"This result gives the largest conceivable amount of urea in the body of a uræmic man weighing 150 pounds.

"In other words, if urea is the cause of uræmia we are forced to admit that nature can accomplish a result, with less than $\frac{1}{5}$ of a pound, to produce which artificially nearly eight times as much is required. The absurdity of the proposition needs no comment. I will not detain you with the many clinical arguments which might be adduced on this question."

Dr. J. C. Peters remarked that the quantity of urea daily excreted by the human adult was four hundred and eighty grains, and the question might arise how large an accumulation could occur in cases of uræmia extending over many months, and perhaps years.

Dr. Peabody said that, of course, no single examination of the blood could determine the exact amount of urea present in the circulation. The observations to which he had referred had been made upon the uræmic blood of patients dying with cholera, and he thought that we must take their estimate of the quantity of urea retained in the blood as nearly correct. Of course, it was quite impossible to simulate artificially the various changes in the kidney structure which are present in what is called uræmia, but he thought all who had paid attention to the subject must have seen cases of total suppression of the urine without any impairment of the intelligence or the occurrence of convulsions, and the patients died usually with fever.

Dr. Van Gieson thought it wise to have a conservative scepticism with regard to the method in which uræmic convulsions are produced artificially. Whether urea may or may not be present in the blood in the condition known as uræmia, one fact remains, that after certain changes have taken place in the kidney which seem to prevent the excretion of the urea, such patients are peculiarly liable to convulsions. For example, in the kidney troubles in which there is a small amount of organic change revealed by the microscope, but there is urine with constantly low specific gravity, such cases are peculiarly liable to fulminate at any time in uræmic convulsions. If one would take the trouble in such cases to estimate the quantity of urea in the urine, it would be found to be very much below the normal—probably one-third, if not one-half, less than normal—and yet the quantity of urine excreted is reasonably large. It had

seemed to him that the cause of these convulsions was the retention of a certain quantity of urea which should have been excreted.

He thought that the evident absurdity demonstrated by Dr. Peabody with reference to the experiment which had been performed by the French experimenters was perfectly in order.

Dr. Prudden thought one point should be emphasized in comparing pathological experiments upon animals with pathological conditions naturally produced. It was not fair to assume that a given quantity of urea put into the blood would produce the same effect which the same quantity would produce when left in the system in consequence of disease.

Dr. Peabody would like to say that Fort, and several other observers, had produced all the symptoms of uræmia by the injection of benzoate of soda, sulphate of soda, and several other agents which were innocuous when taken in ordinary doses, and he thought that the results of the French experimenters were those which would have been obtained by the injection of other substances than urea. By injecting some foreign substance in enormous quantities they have produced convulsions, coma, and death, but had not contributed anything at all to our knowledge of the method in which the symptoms of uræmia are produced. Of course, these physiological experiments were not to be compared with the conditions produced by disease, and that was the point which he wished to make, that it was not the urea circulating in the blood which produced the clinical phenomena, but the pathological condition of the kidney.

Dr. Peabody also presented a specimen of

ABSCESS OF THE LIVER.

The patient was an Irish laborer, married, and forty-eight years of age, who was admitted to the New York Hospital September 11, 1884. He stated that his parents and other members of his family were alive and well, and so far as he knew there was no disease in the family. Nine or ten years ago he had been sick for about twenty-one days, having a fever accompanied by chills and sweating. With this exception his health had always been good. He had always been accustomed to drink to the extent which he called "moderate," and he denied syphilis.

Five weeks ago, while drinking more than usual, and eating insufficiently, he began to have attacks of vomiting and diarrhœa. For the last three weeks he had in addition a cough and feelings of weakness, and, at irregular intervals, slight chills. These symptoms had lasted to the date of his admission.

On admission (1 P.M.), temperature, 103.6°; respiration, 36; pulse, 120. Patient was poorly nourished, had no œdema. He was very stupid and drowsy, and when roused spoke in a very thick, indistinct voice.

On physical examination no cardiac lesion was detected, and in the lungs only bronchial râles and crepital râles at base of chest on both sides behind. There was no apparent abdominal lesion. Over the skin of the abdomen and back there was an eruption of small red papules, and in some places pustules. There was no itching. Urine was normal. In the evening he had a chill, his temperature rose to 104.2°, pulse and respiration being substantially unchanged. His tongue was heavily coated. He was given quinine in ten-grain doses, and subsequently arsenic, and for several days he slowly improved in general condition, his temperature remaining in the morning between 100° and 101°, and in the evening not going beyond 102°.

A week after his admission his tongue got dry and brown, and his pulse became feebler. Under digitalis he brightened up, however, his pulse improved, his temperature dropped to 99.8° and did not go above this point for several days; he grew hungry, and at his own request was allowed solid food. On the 21st of September he grew decidedly weaker, sordes collected about his teeth, but his temperature remained low, *i.e.*, under 100°. On September 23d his pulse began to grow irregular, his temperature rose to 100°+, and his stupidity increased. He continued to fail, and his breathing became labored. Stupidity deepened into coma during the night, and he died at five o'clock on the morning of the 24th, his temperature having steadily risen during the last few hours of life to 105.2°.

He was constipated during most of his hospital career, and was given cathartics with temporary relief, and nothing characteristic was noted in the color of his stools. He was frequently sponged with alcohol and water for his fever, and was freely stimulated.

"I have given you as fair a representation of his condition as I can, the prominent features of his case being all dwelt upon, and now I have to ask if there is sufficient basis for a diagnosis. For me there was not. Taking all the points into consideration, it seemed to me that the man, who was very ignorant, might have had a mild attack of typhoid fever three weeks previously, and might, on his admission to the hospital, have been suffering from a relapse.

"The autopsy was made nine hours after death. The only facts which are important are these: 1. The spleen was large and soft. 2. There were, as you see here, two large abscesses in the liver, the larger being in the right lobe just beneath the diaphragm and containing about half a pint of pus and necrotic liver-shreds, the other being in the left lobe and somewhat smaller. In the portal vein, in close proximity to the larger abscess, is a firm thrombus of considerable size. 3. There are several small, well-defined ulcers in the large intestine, scattered all the way from the cæcum down to the sigmoid flexure, all apparently in process of healing.

"The relations of these lesions to one another, and to the clinical symptoms, are now simple enough; but it seems to me that this is another obscure case of abscess of the liver whose diagnosis was practically impossible."

Dr. Carpenter asked Dr. Peabody if he regarded the relation which existed between the intestinal ulcers and the abscess of the liver as that of cause and effect.

Dr. Peabody replied that he did.

Dr. Seguin asked Dr. Peabody if the patient was melancholic.

Dr. Peabody replied that he was very lethargic, and presented very much the appearance as though he was suffering from a relapse of typhoid fever.

Dr. Ferguson presented a specimen of

OSTEO-SARCOMA OF THE RING FINGER.

The patient was admitted to Dr. Little's service at St. Luke's Hospital, August 28, 1884. Six months previously he struck the tip of his right ring finger on the floor. No deformity was produced at the time, but a tumor gradually formed. It had never been painful. On admission there was an ovoidal mass the size of a duck's egg upon the first phalanx. The skin was normal. The tumor felt boggy, and gave an expansive pulsation. On September 9th, the finger was amputated by Dr. Little, and on microscopical examination made by Dr. Ferguson, Pathologist to the hospital, the tumor was found to be composed of spindle and round cells, with a great number of giant cells.

Dr. Ferguson presented microscopic sections which showed the giant cells in great abundance. These cells in places were closely aggregated, while in other places they were represented by granular and homogeneous substance. The tumor was limited by a fibrous capsule, and the bone was not distinguishable except in mere fragments.

Dr. Ferguson also presented a specimen of

SARCOMA OF THE KIDNEY

removed from a child four years old. The case had already been reported by Dr. Little.

Dr. George A. Dixon presented a specimen of

ANEURISM OF THE ABDOMINAL AORTA.

C. S——, female, native of Ireland, twenty-seven years of age, married, housekeeper, was admitted to Charity Hospital November 18, 1884.

Family history.—Father died of consumption; mother was living and well; brothers and sisters all died young.

The previous history of patient up to May, 1883, was good. At this time patient noticed a pulsating tumor on the inner side of her right thigh; felt some pain just below and to inner side of tumor; also had some pain just below right knee and in ankle. The swelling increased rapidly and at times pain was so severe that she could not walk. For this trouble she entered St. Luke's Hospital on July 5, 1883. She gave no history of any injury, alcoholism, or of syphilis. She stated, however, that in carrying tubs of water or clothes she rested the sharp edge of the tub on her right thigh. There was no weakness of the leg; her general health was good. Heart, lungs, and kidneys normal. Menses had always been regular. Never had any children. The circumference of thigh over the tumor was twenty-one and three-eighths inches. Diagnosis was femoral aneurism. This was treated by digital compression on cardiac side of aneurism, pressure being constant for twelve hours. At the end of this time tumor was one inch smaller, hard to the feel, and there was no pulsation, bruit, or sense of fluctuation. Twenty-four days after this treatment patient was discharged cured, thigh measuring nineteen inches; tumor was firm and there was no sign of pulsation. From this time up to August, 1884 (a period of a year), deceased remained perfectly well, doing general housework. Then noticed that her "courses failed," that she had pain in her back and legs on walking, also in abdomen. Appetite failed, and she was troubled with nausea and occasional vomiting. These symptoms increased in severity, and in October, 1884, patient noticed a "pulsating lump" in her abdomen, for which trouble she entered Charity Hospital.

On admission, November 18th, patient was weak and anæmic, no appetite, bowels constipated, vomited a great deal. Could not sleep.

Physical examination.—Heart: there was a slight systolic murmur; lungs, liver, spleen, and kidneys normal. Abdomen: inspection showed a pulsating tumor in epigastric region; by palpation there was felt a distinct impulse occurring with second sound of heart, and on auscultation there was heard a double bruit. The original seat of the femoral aneurism was examined, and no tumor or pulsation was found.

The patient was put on tonics and ordered to remain in bed. Nothing unusual was noticed until the evening of November 20th, when the patient became pale, complained of shortness of breath, rapidly became collapsed, and died early the following morning.

Autopsy.—Brain not examined; lungs normal. Heart: slight hypertrophy of the left ventricle; aortic valves slightly thickened. Liver: a little increase of connective tissue. Kidneys: early stage of interstitial nephritis. The aneurismal sac in the abdominal aorta extended from the cœliac axis to a point three-fourths of an inch above the bifurcation of the aorta into the iliacs. The sac was spheroidal, measuring ten and a half inches in circumference. The inner wall of the sac was covered by laminated fibrin. With the exception of one-fourth of an inch on the left side, the entire wall of the aorta was involved in the aneurism. On its anterior surface was a rupture an inch and one-fourth in circumference. To the right of the sac and on its anterior surface was a large mass of coagulated blood. The aorta immediately above the aneurism was atheromatous. Below the aneurism there was a constriction in the aorta, which would not admit the little finger; this constriction was an inch in length, and its lower end was one and one-fourth inch above the bifurcation of the vessel. The ascending vena cava was moderately distended.

FIBROID TUMOR OF THE UTERUS.

Dr. H. C. Coe presented two specimens, which represented two different operations. In the first Hegar's operation was performed, and the ovaries removed close to the tumor. The patient died seven days after the operation from peritonitis. The most interesting feature of the specimen was that, at a point on the anterior surface of the fundus of the uterus, there could be seen a large cicatrix. What it was due to he did not know. There was no history of the patient having been tapped or otherwise operated upon previous to this operation. In the second specimen the entire uterus was removed. There was a fibroid in the posterior wall. It was really the beginning of a fibro-cyst. The patient died on the eighth day after the operation.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CHARCOT'S JOINT DISEASE AND THE DEBATE AT THE CLINICAL SOCIETY—SPEECHES BY MR. MORRANT BAKER, MR. ARTHUR BARKER, DR. DYCE DUCKWORTH, DR. HALE WHITE, DR. BUZZARD, MR. BARWELL, SIR JAMES PAGET, DR. ORD, PROFESSOR HUMPHRY, MR. HUTCHINSON, AND MR. HULKE.

London, December 10, 1884.

The chief topic of interest in the field of scientific medicine just now is "Charcot's disease" and its pathological position and relations. This has been discussed at two meetings of the Clinical Society, and on the last occasion the debate was again adjourned, so it will probably occupy another evening.

Charcot's first case was described by him in 1868, a second in 1873. In this country Dr. Clifford Allbutt recorded a case in the same year in which Charcot's first case appeared. The next one was published by Dr. Buzzard in 1874. Since then several cases have been observed, and papers on the subject have appeared in different journals, but it is only within the last three or four years that the affection has become generally known, even among hospital physicians and surgeons.

Mr. Morrant Baker set the ball rolling by reading a paper on "Three Cases of Joint Disease in Connection with Locomotor Ataxy." In all the symptoms of ataxy were well marked, and in all the joints affected were in a condition apparently typical of Charcot's disease. In two of the patients (both males) the joint most involved was the right knee-joint; in the third patient (a female) the right elbow and both hip-joints, there being also commencing disease in the left elbow-joint. The joints were enlarged, their articular surfaces considerably worn away, and the ligaments weakened or destroyed, so that the joints were loose or "flail-like." In the case of the elbow and knee joints, however, considerable power of voluntary movement was retained. In connection with "Charcot's disease," Mr. Baker thought the following points were worthy of discussion: 1. Was the disease new? 2. What were its alliances, if any, with rheumatoid arthritis? 3. If connected with rheumatoid arthritis, was its occurrence in conjunction with locomotor ataxy a mere coincidence, or did they stand in the relation to one another of cause and effect? 4. If connected pathologically, both with rheumatoid arthritis and locomotor ataxy, should not all cases of rheumatoid arthritis be considered as neurotic in origin, whether accompanied or not by symptoms of locomotor ataxy?

These points were sufficient to lay open a very wide field for discussion, but Mr. Barker remarked before concluding that still another theory was possible, even if Charcot's disease, locomotor ataxy, and rheumatoid arthritis were all connected. He suggested that they might all arise from some antecedent morbid condition, the result of which was seen in pathological changes which occurred, sometimes in the joints, sometimes in the nervous system, sometimes in both.

Mr. Arthur Barker then narrated the case of a porter who suffered from urinary and gastric troubles. Numb-

ness in the feet and "rheumatic" pains in the limbs were complained of. A perforating ulcer of the right foot came on. There were no other symptoms of ataxy. When next seen gastric troubles were again complained of, and the foot was worse. Shooting pains in the left thigh came on. One of the knee-joints soon became completely disorganized. Up to the present time the knee jerks had not been lost, there were no eye symptoms, and none of the ordinary signs of ataxy.

Dr. Duckworth maintained the non-identity of Charcot's disease with rheumatic arthritis. Clinically, they were very different, and he remarked that identity of lesions was by no means a proof of identity of processes leading to the lesions.

Dr. Hale White referred to a case in which he had found on post-mortem examination, changes in the temporo-maxillary articulation indistinguishable from those of Charcot's disease; the other joints were equally unmistakable examples of rheumatic arthritis.

Dr. Buzzard commenced a lengthy speech by stating that, in his opinion, the disease was not new. He had carefully looked through Graves' work and had unearthed a case which was marked by typical gastric crises, and which he considered was without doubt one of locomotor ataxy. This case was observed in 1823. As cases were little recorded formerly, population was smaller, and hospitals had no out-patient departments, it was not strange we should come across more cases in proportion now.

Dr. Buzzard maintained the existence of Charcot's disease distinct from rheumatic changes. He described the osseous changes met with by Lionville in cases of ataxy. There was dilatation of the Haversian canals with thinning and erosion of the bones. Regnard had, on chemical examination, found the inorganic constituents of the bones reduced in amount and replaced by fat. Dr. Buzzard suggested that to distinguish Charcot's disease from rheumatoid arthritis, the specific gravity of the bones should be observed; it would probably be found lessened in the former. He defended Charcot's views, and said that he had never found the knee jerk absent in cases of rheumatoid arthritis.

Mr. Barwell resumed the adjourned debate. He said he could not follow Mr. Baker in his speculations, except so far as to agree that arthritis deformans was associated with some form of nerve-lesion. He maintained the dissimilarity of Charcot's disease and rheumatoid arthritis, both on anatomical and clinical evidence. In the former the processes of repair were very different from those occurring in the latter; false bodies were not met with in the joints, and the fibrous degeneration of cartilage and synovial outgrowths met with in rheumatic arthritis did not occur. Clinically, the sudden, rapid, painless swelling of tabetic joints, the length of time the effused fluid remained, and the excessive amount of false movement were striking distinguishing features. Ataxic conditions never affected small joints of the hand or foot; in rheumatoid arthritis these were specially selected by the disease, and the peculiar deformities of the fingers and the twist to the ulnar side were characteristic.

Sir James Paget said he was able to agree with Mr. Baker in almost every point raised. On the question of the novelty of the affection, he considered that Charcot's disease was a new malady. He was unable to think that the older workers in the field of pathology were likely to have been blind to the occurrence of such examples of injury, had they existed for them to see. The experiences of the older surgeons were derived from the study of diseases among the same classes of patients as now thronged our out-patient departments. It was in infirmaries, workhouses, etc., that Hunter, Howship, Cruveilhier, Stanley, etc., were wont to search for fresh additions to the science they were constantly cultivating. Sir James Paget said he had himself searched in vain for any record of the disease. On the subject of the neurotic connection of the lesions, it was necessary to recollect that it presented an assemblage of numerous relations. While on this point he insisted that the fact of a disease being known by the name of a person or a country was an indication of its pathology being imperfectly understood. As instances he cited the terms "Bright's disease," "Morbus Anglicus" for rickets, "Morbus Gallicus" for syphilis, all of these now nearly obsolete. Sir James Paget regarded Charcot's disease as in effect rheumatoid arthritis modified by conditions associated with ataxy, and the relationship of the two was exhibited by intermediate cases, the shades of which were of such a kind that it might be difficult or impossible to determine whether a given specimen was to be classified under the head of one or the other disease. Syphilis was often associated with locomotor ataxy, so that in the production of the disease under discussion three elements might be concerned. It should also be borne in mind that the course of syphilis might be modified by diathesis running a very different course, for instance, in gouty persons as compared with tuberculous subjects.

Dr. Ord agreed with Mr. Baker, but went further and considered repair might and did occur. In the diseases of the joints under discussion he contended that strong evidence existed to indicate that in them neuroses played an important part.

Professor Humphry agreed with Sir James Paget in regarding the disease as new. He was of opinion that it was compounded of rheumatoid arthritis and locomotor ataxy. Wearing away of the structures, and low inflammatory changes, were apparent in chronic rheumatoid arthritis, but the changes were infinitely more rapid and complete in tabetic arthritis.

Mr. Hutchinson said that at the outset he agreed with Charcot concerning the neurotic origin of the disease, but could not now accept this explanation, preferring to regard it as originating in causes leading to rheumatic gout associated with senile changes. Eburnation and formation of osteophytes occurred almost always in old people, and Mr. Hutchinson regarded locomotor ataxy in some cases as "tumultuous old age" associated with a remarkable loss of sensibility. Sensation was dulled in ataxics, and hence arose retention of urine, and also the perforating ulcers of the foot in them, these being due to continued pressure on the insensitive part, as shown by the ready manner in which such ulcers healed up when pressure was removed. There were well-marked differences between chronic rheumatic arthritis and tabetic joint disease, excessive painless mobility of the joint being peculiar to ataxy. But there were many cases merging into one or other form, and Mr. Hutchinson possessed proof of the occurrence of chronic rheumatic arthritis in tabetic subjects. Insensibility to pain was an important factor in producing tabetic arthritis, for ataxics persisted in moving about because they had no pain in doing so: and thus the condition of joints peculiar to Charcot's disease was set up, being "permitted" by, though not "caused" by, the nervous system.

Sir James Paget (in reply to a question from the President, Sir Andrew Clark) said he was indisposed to think that arthritic changes in ataxy owed their origin to the nervous system further than by its "permitting" disease. The nervous system could *determine* the occurrence of disease (as shown in herpes zoster), but not its mode of evolution.

Mr. Hulke could not agree that Charcot's joint disease was distinct from chronic rheumatic arthritis. He showed specimens of bones obtained from the same subject, some of which showed all the signs of Charcot's disease, and others, of chronic arthritis. Either the two diseases were both present or else they were identical. In reply to Mr. Barwell's statement that only the large joints were affected in tabes, he cited a foot exhibited by Professor Charcot, in which all the small joints were degenerated. He agreed with Sir James Paget that syphilis was a factor in causing the disease.

THE PROGRESS OF MEDICAL SCIENCE AND A NOVEL URINARY ANALYSIS.

To the Editor of The Medical Record.

Sir: A bottle of urine was sent me a few days since with a request for microscopical examination. The gentleman making the request wrote that the urine had been examined by an expert, but it had been done some months since. and he kindly enclosed a copy of the expert's report, which I have again copied *verbatim et literatim*, and send herewith. I do not know as it will contribute anything to the instruction of your readers—though it may amuse them.

"Report. The urine contains excess of phosphates, Epithelium, granular and Hyaline Casts. Albumen hematin Pus corpuscles, Some spermatoza cholestearine biliverdine uric acid in Large quantities.

"the urine is acid sp. G. 1005.

"This shows that you are suffering from Chronic Nephrosis of the Kidneys and Addison disease of the super Renal Capsules with a tendency to Bright's disease or Albuminuria.

"I shall not prescribe as you have your own doctor. I recommend Vichy water pretty freely. ———."

Maurice N. Miller, M.D.

Laboratory Normal Histology,
University Medical College, New York.

A REMEDY FOR THE MANURE NUISANCE.

To the Editor of The Medical Record.

Sir: It does not seem to me that the plan adopted by our Health Board is likely in the near future to rid this city of the manure-dump nuisance. The plan is only the old one called up, which all know *signally* failed, and will fail every time that it is applied. Any of our citizens, who know and can comprehend the difficulties of gathering and shipping this great mass of débris of our city by the present system, can discern that it is not possible, and that places for storage are absolute necessities. In the winter season, when there are at times several miles of ice-floes in the river, and also when heavy gales are blowing, how, I ask, are scows to get to and from the wharfs with safety?

I know that I need not press these interrogatories any further: the reasonable will understand. It is very plain that either another plan must be devised and executed, or we must put up with the present nuisance as the best that can be done, and let our manure gatherers go on in peace. The plan which I think most feasible is the one which I suggested several years ago, and would, in my opinion, if earnestly carried out, relieve our city of all offensiveness connected with this business, which is, to require all this material to be *pressed* into bales *in* the *stables* where it accumulates. This simple process stops fermentation in the substance, and renders it as inoffensive as dried earth, and in a condition to be stored in stable-lofts or adjoining sheds when necessary in considerable quantities. These bales may be made up to weigh about two hundred and fifty or three hundred pounds, or of any other size convenient to handle. The requirements for this are not at all expensive or complicated. The ordinary *hay-press* will answer for both manure pit and press, and can be placed anywhere on the stable-floor; when the box is sufficiently filled the lever can be applied. To hold the bale intact the ordinary bale-stick and wire are all that is necessary.

The advantages of this plan, I think, will be apparent to every one who gives it thought. The dumps can be dispensed with; the article can be either stowed where it is put up, or on the wharf under sheds, ready for shipment. The bulk will be largely reduced; the means for transportation greatly lessened, the manure-pits in the stables, or in many of them under the sidewalks, entirely done away with, and the farmers and gardeners who buy this article have the privilege of composting it on their lands, thereby saving much of the virtues which otherwise are lost. In a sanitary point of view, I do not think we have ever properly investigated the noxious influences of the manure-pit—a necessary appurtenance of every stable. It is a well settled fact that decaying vegetable and animal matter, mixed and in a state of fermentation, is highly deleterious to the health of both men and beasts. Horses become blind from ophthalmia, and succumb to diseases of the air-passages; and human beings, from ailments closely allied to these, both suffer and die when subjected to an atmosphere charged with emanations from decomposing heaps of stable débris for any considerable length of time. How many of the lower and exhausting forms of disease which afflict human beings can be traced to stables where animals are housed in large numbers, has not yet been satisfactorily determined, but that some have been, is too certain to be longer doubted.

Alexander Hadden, M.D.

155 East Fifty-first Street.

THE TREATMENT OF GOITRE.

To the Editor of The Medical Record.

Sir: I have read with interest your editorial concerning the treatment of goitre in The Medical Record of November 29th. The disease is, as you remarked, becoming more common in this country. I think that in the counties along our great lakes the largest proportion of cases will be found, without regard to foreign influence. The climate in those regions seems to be exactly suited for the development of scrofulous diseases, and I have noticed an unusual number of crippled and feeble-minded folks. The general appearance of the natives has attracted my attention more than once—the small chins and weak bone-development suggesting something more than poor nourishment. I have attributed this condition in many, to our lake region climate. This may not be the rule, but certainly I have noticed so many cases in towns and villages along our great lake coast that I have failed to be favorably impressed with any of the lake resorts as *health* resorts. To return to the subject of goitre: we have, then, in this country an increasing number of cases of this dreadful disease. The miserable, unsanitary lives led by many of our poorer classes is one cause. Poor food, unhealthy homes, insufficient clothing, bad drinking-water, filthy living habits, severe, damp, chilly atmosphere, all these are favorable to the development of this disease. While in Switzerland I had repeatedly noticed that in districts where goitre seemed most prevalent these same causes could usually be found present. In summer and in winter I have found these Swiss homes anything but the poetic picture of cleanliness and beauty they are usually represented to be. Of course, goitre is not *confined* to the poor and lowly any more than other diseases are. We have all classes suffering from it. but the great majority are those who live in a very unhealthy, uncared-for way, and on this account it is hardly fair to saddle the blame on the clear, beautiful streamlets rippling down to the villages, bent on missions of life and cleanliness and *not* on disfigurement and death. In the treatment, change of life, a radical change, is imperative; change of climate, usually, sanitary improvements in general. Then change of food, iron tonics, and, best of all local treatments, the use of *electricity*, applied daily for thirty to sixty minutes or longer, until the tumor is actually dissolved; and very often, the preliminary treatment having been faithfully carried out, the local treatment will succeed. Parenchymatous injections of any fluid are never advisable, and cannot be so successful as the course already indicated. As you have said, "Experience has shown that iodides will prove of decided and lasting benefit only in those cases where marked effects quickly follow their first use." In all cases the treatment by iodides, *after* the preliminary tonic course and hygienic improvements necessary, is good practice; but

the use of electricity *locally* will afford remarkable success. The subject is an important one, and its discussion must bring forth some practical results. For the use of electricity I must give Professor W. T. Plant, of Syracuse, N. Y., the full credit. Some years ago he showed me a case doing remarkably well under treatment by electricity. This case suggested some further experiments, and I believe that patient use of the treatment suggested will be very satisfactory. I do not know whether Professor Plant's case recovered or not, or whether it has been reported in our medical journals; but the treatment since then of other cases deserves careful consideration.

Very truly yours,

W. Thornton Parker, M.D.

CONCERNING LARGE DOSES OF IODIDE OF POTASSIUM.

To the Editor of The Medical Record.

Sir: In your issue of December 6th, page 641, there appeared a communication from my friend, Dr. Otis, presenting a contribution to the question of priority in giving large doses of potassium iodide. Not having any personal interest in this question I should be glad to be instructed and corrected; but I must say that Dr. Otis' letter quite fails to do the latter. In the first place, let me say that it is somewhat doubtful if Dr. Otis had read the original paper at the time of penning his communication, for he quite misapprehends the questions at issue, and duplicates one of my quotations. He quotes the misprint as to "large doses," which appeared in your editorial of November 1st, page 492. This states: "By large doses is meant such as make up a total of from two and a half to ten grammes in twenty-four hours." A reference to the opening paragraph of the original (*Archives of Medicine*, xii., p. 115) will show that I wrote "from 3 ijss. to 3 x.," a vastly different amount. This fundamental error leads Dr. Otis to do some unnecessary criticism. He quotes Ricord as having given up to six grammes in twenty-four hours, which is not equal to my minimum "large dose." I had quoted Ricord (from Trousseau and Pidoux) as giving from fifteen to sixty grains a day. Dr. Otis also quotes Lancereaux as against my statements, not noting that I had given the very same quotation from the original; and Dr. Otis is careful to omit stating that Lancereaux condemns the larger doses.

Referring to Hill and Cooper as recommending large doses in 1881 hardly helps the historical inquiry. Dr. Otis writes as if I had made statements as to who first used "large doses" of KI. This was not my object, and I knew very well that some (unknown) physicians had used very large quantities of the drug in syphilis before Van Buren, as is shown by my own quotations from Lancereaux, Nothnagel and Rossbach, and from Fournier. These authorities all make vague and anonymous reference to such dosage, and they all object to the practice. My purpose was to discover who first established, by teaching and by personal influence, the *method* of giving large doses, and in doing this I sought reliable printed and oral testimony. That Dr. Crawcour (and many others) may have used as large doses as Van Buren many years ago I did not and do not deny; but there is no evidence that they succeeded in inducing others to do likewise, or that they publicly taught its necessity.

First.—As to Dr. Otis' own claims. He certainly is to be ranked with those who have for a few years used the large doses of KI, but so are scores of other surgeons and physicians, and I could not burden my essay with such a list of names. I will go further and say that nowhere has Dr. Otis published his teaching on this point. In his various valuable contributions to syphilography in files of The Medical Record and the *Boston Medical and Surgical Journal*, the question never comes up, and he himself can only refer to passages in a work of his appearing in 1883—altogether too late to give the author any special claim to be classed with the promoters of the method. In 1879–80, Dr. Otis published in the *Boston Medical and Surgical Journal* a series of "Clinical Lectures on the Physiological Pathology of Syphilis." The eighth lecture, vol. ciii., p. 317, treats largely of the utility of the iodide of potassium, yet in the three columns devoted to this drug not one word is said of the advisability of using "large doses." The same is true of the republication of these lectures in book form by Putnam, in 1881. Pages 86 to 91 are occupied with remarks about KI and its *modus operandi*, but the author's views about large doses are vainly looked for.

Dr. Otis has doubtless taught this method orally, but he makes a *lapsus calami* in stating how long: "I have for the past twenty-five years taught this plan of treatment for the late lesions of syphilis in my clinic at the College of Physicians and Surgeons;" but the official records of the College show that Dr. Otis was placed in charge of the clinic for venereal diseases in September, 1870, only fourteen years ago.

Prior to that time the clinic was in the hands of the distinguished Dr. F. J. Bumstead; and to show how recent has been the spread of the practice of giving "large doses" of the iodide, I would state that Dr. Bumstead, in 1871 ("Hints on the Treatment of Syphilis," *Am. Practitioner*, cited in New York Medical Record, vol. vi., p. 370, 1871), recommends from thirty to fifty grains three times a day, and states that he has never given more than three drachms in one day.

As regards Dr. Kelly's claim. It has some merit as a claim from private practice, but there is no evidence whatever that he exerted any influence upon his contemporaries or successors; nor has any printed teaching of his been produced. I admit, from Dr. Otis' statements, that he was one of many who employed "large doses" of KI in the treatment of syphilis before Van Buren, Keyes, and Draper, but I decline to go farther. Besides, if Dr. Kelly should be shown to have been the originator of the method, my claim that it is an American method is not shaken.

Second.—If any injustice has been done, it is not to any gentleman yet named, but to Dr. M. H. Henry, of this city; and I am glad that the necessity of writing this note gives me the opportunity to make a correction. Dr. Henry, in 1872, published a paper entitled, "Clinical Observations on the Dementia and the Hemiplegia of Syphilis," in the *Journal of Syphilography and Dermatology*, vol. ii., p. 5. This was two years after Dr. Keyes' paper, and at a time when very few physicians gave "large doses" of KI. I quote Dr. Henry's remarks upon his first case: "I have been somewhat surprised to find that, even at this time, there appears to be some fear shown by our friends on the other side of the Atlantic of the use of the large doses (of KI), such as we are in the habit of using in this country, and this, too, since Sir Henry Thompson published (*Lancet*, December 28, 1867) his own excellent conclusions. To derive the full benefit of the iodide where there is a large amount of gummy deposit, or any of the inveterate and intractable forms of the disease in the tertiary period, it must be given in large doses; indeed, I scarcely know the limit. Little fear need be entertained about producing iodism. I have never seen it in a person suffering from tertiary syphilis. In this case (Case I.) the patient took three hundred grains daily for more than eight weeks, and with the disappearance of the symptoms he gained steadily in his general health and in flesh. To obtain the best results in the use of the iodide it should be taken thoroughly diluted, each dose in a small glass of water." This is very clear and sensible. Surely Dr. Henry should share with the gentlemen I named the credit of being among the first to teach the method of large doses of iodide in syphilis.

Third.—As to the time of administration of the

iodide. I have already taken up so much space that I will only say that this is a question each practitioner can decide for himself. I believe in the correctness of my plan, of giving the drug largely diluted (in an alkaline vehicle if possible), *before meals*, and others are pleased with its results. Still, I recognize exceptions to such a rule, and have met with a very few patients who stated that they could take the iodide more easily after meals.

Yours very truly,

E. C. SEGUIN.

December 27, 1884.....	0	12	70	5	81	56	0	0
Deaths.								
December 20, 1884.....	0	10	24	6	28	31	0	0
December 27, 1884.....	0	3	22	3	16	36	0	0

CHLOROFORM TREATMENT OF TAPEWORM.—Dr. F. J. Croner, of Big Rapids, Mich., writes: "My patient was a delicate lady with a specially delicate stomach. I prescribed on November 27th: ℞. Chloroform, ʒ j.; olei tiglii, gtt. ss.; emul. olei ricini, syr. acaciæ, āā ʒ jss. M. This was given after twenty-four hours' fast, and in six hours the worm was expelled. No bad symptoms."

THE CLIMATE OF SOUTH CAROLINA.—Dr. W. H. Geddings, of Aiken, S. C., writes in reply to Dr. Samuel Aug. Fisk's criticism of Dr. Loomis in THE RECORD of November 8th. Dr. Fisk takes Dr. Loomis to task for saying in his "Practical Medicine" that Southern California, Georgia, and California have "a dry, warm atmosphere." Meteorological reports show for Augusta, Ga., 69.2°; Jacksonville, Fla., 69; St. Paul, Minn., 67.3; Denver, Col., 45.8° per cent. of saturation. Dr. Geddings concludes that Dr. Fisk has taken the figures for Augusta, Ga., to represent the climate of Georgia and South Carolina. But Augusta being situated upon a river in what was once a swamp, its records do not fairly represent the atmospheric condition of Thomasville, Ga., and Aiken, S. C., which are situated in the sand hills at a higher elevation away from any water. "But," adds Dr. Geddings, "more important than these physical features are the results of observations with the wet and dry bulb thermometers. The mean annual relative humidity of Aiken, as determined by this instrument, is 58° while that of Augusta, according to Dr. Fisk, is 69.2°, a difference of over eleven degrees. As 55° relative humidity is ranked, by such authorities as Vivenot and Hermann Weber, as EXCESSIVELY DRY, it is difficult to understand how Dr. Fisk arrives at the conclusion that this portion, at least, of South Carolina '*cannot be called dry*,' but the doctor adds, 'certainly not in comparison with the dry air of the Rocky Mountains regions.' No, nor is it subject to the fearful vicissitudes of temperature incidental to all excessively dry climates, nor does it have the annoying sand-storms, of which visitors to Colorado complain so much."

WHEN DOCTORS AGREE.—Dr. John Godfrey, of New Orleans, sends us a poem read at the annual banquet of the New Orleans Medical and Surgical Association. We regret that we only have space for a concluding verse:

> "You all have heard the time-worn plea,
> That no two doctors can agree,
> Through imperfections.
> Let no such thought your mind deceive,
> For doctors one and all believe
> In prompt collections."

THE MODE IN WHICH PATHOGENIC ORGANISMS ARE CULTIVATED IN BERLIN.—As is now well known, courses of demonstrations have been recently given in the Imperial Health Office of cultures of micrococci, and of the methods employed in this department of scientific research. Owing to the want of space the demonstrations were held in separate sections, each section being presided over by some well-known investigator. A short account from an eye-witness of what was seen in the section presided over by Dr. Loeffler, and for which we are indebted to the *Deutsch Med. Zeit.*, will not be without interest at the present time. The speaker first referred to the important part played by solid nutrient soils in the elucidation of the problems connected with micro-organic life. He held that the potato formed the most suitable soil for many forms. The potato is first washed and thoroughly brushed, and then, after the eyes are cut out, it is left for half an hour in 1.1000 solution of sublimate. It is then placed in a sterilizing vessel of tin and copper for half an hour with steam. This kills all forms of germs, even the so-called permanent or resisting spores. The speaker gave an illustration of the inefficiency of dry heat in destroying germs. He at one time received a letter from the Cholera Commission, and upon a piece of paper within the envelope some micrococci from the intestinal canal of an ape. The letter passed the disinfecting station at Brindisi, was then thrust through in several places, and for a length of time exposed to dry heat for the purpose of disinfecting it. After Dr. Loeffler received the letter, he sowed the micro-organisms on a suitable soil, and although some of the micrococci were dead, from the places where they lay more thickly on the paper a rich harvest of cocci developed.

The potato thus sterilized is now cut across with a freshly heated knife, care being taken that the surface does not come into contact with the fingers. By examination with a strong light, the species of micrococci may be recognized by the form and grouping of the colonies. In order to transplant a particular kind of micrococcus, a small portion is taken off the potato surface with a recently heated platinum needle, and implanted upon a fresh potato, which is then placed upon a shallow glass dish moistened with sublimate solution and provided with a cover glass, covered within with filter paper. In this "moist chamber" the pure cultivations develop rapidly at a proper temperature. As a fluid nutrient soil, either the usual gelatine or agar-agar, or Ceylon moss, is made use of.

Original Articles.

ON THE UTILITY TO PATIENTS SUFFERING FROM PULMONARY PHTHISIS OF INTRA-PULMONARY INJECTIONS.[1]

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

DURING the early part of last spring I was asked by a member of the Council of the Climatological Society to read a paper before that association in Washington, in the month of May, on "The Present Limit of Lung Surgery." I undertook the preparation of this paper, mainly because I was much interested in the different aspects the subject presented, and notwithstanding the fact that my personal experience at the time was very limited, and, indeed, confined to a few cases of phthisis pulmonalis, in which I had made intra-pulmonary injections.

Following the request made of me by the Climatological Society, I read through, and carefully annotated, the literature on the subject which had been assigned me. The paper, however, was not completed in time to read it before the society, and has remained ever since in my drawer, awaiting an opportunity to revise, correct, and bring it up to date. At best, and *in part*, it was and is nothing more than a critical review of what others have written and done. In reference, however, to the subject of intra-pulmonary injections, I have obtained some additional experience, and, although my views are not yet determined in regard to their precise indications and utility, I thought it best (when I was requested by our Secretary to take the place of another member) to read a short paper before you to-night, and to offer any additional views I may hold, and which subsequent discussion may prompt me to bring to your attention. I would here add one word, and it is to crave your extreme indulgence for the incomplete study of my subject and its somewhat discursive presentation.

Remember that I regard my actual observations merely as a kind of preliminary report of future work to be done by myself; and I desire simply, at the present time, such a discussion by you with respect to intra-pulmonary injections as may place the operation itself upon a legitimate basis, and enable us all to recognize clearly our duty in regard to its employment, and precisely under what conditions we should desire to perform it upon phthisical patients.

My purpose, therefore, is not to treat my subject exhaustively, but rather to bring prominently before this Society a theme of great interest and importance; and after refreshing your memories somewhat with the history of what has hitherto been done in this department of lung surgery, to relate my own experience, and to ask for an expression of views from different members, so as to know how you severally regard an operation which to me appears not only advisable, but, under certain circumstances, obligatory. Before laying before you, however, the history and facts strictly pertaining to the matter in hand, permit me to ask what is our ordinary experience of the treatment of pulmonary phthisis by usual methods?

Is it not deplorable and disheartening to the highest degree? Of course, to the relatively fortunate ones of the world, who are surrounded by all the comforts of life, and who can, at the earliest approach of this dread disease, go and dwell in the most suitable climate, this statement is scarcely true. There, with everything that money can purchase, and tender, judicious nursing bestow, and the careful administration of alterative and corroborant drugs, indicated in such cases, under the care of an instructed physician, the results are occasionally encouraging.

But even with these attendant happy circumstances, in the midst of much pain and weariness of body and mind, is it not still true that the patient must absent himself from the inclemency of our northern winters and springs so soon as the undoubted rational and physical signs of pulmonary phthisis are present, if he may fairly hope for permanent improvement in his bodily condition? How hopeless is the transport of such cases to the sunniest, or the clearest, dryest, and most bracing atmosphere, with continuous equable temperatures, and no raw chilling winds, if the disease has already advanced to the stage of softening, or apicial cavities! Turn aside for a moment from the survey of the patient suffering from phthisis under the conditions just referred to, and contemplate in your mind's eye, as you all can do so easily, alas! and note the almost absolute hopelessness of our *former methods of cure* when applied to many frequenters of our dispensaries, and the occupants of numerous beds in our city hospitals.

Does the continued taking of cod-liver oil and the hypophosphites really cure them? Does painting with iodine or repeated blistering make perceptible changes for the better in the local lesions at the apices, that march so surely onward? I believe we must all say frankly, although regretfully, no! Insist as much as we can upon the necessity of good food, dry, well-aërated rooms with sunny outlook, life in the open air when the weather is fine, care in regard to draughts, to dampness, to wet, to cold winds, and what are the results obtained in these cases? How frequently, moreover, can all healthful indications be rigidly enforced by the poorer classes, and if they really could be, would such patients recover? Rarely, or not at all, if the pulmonary lesion be already advanced, and only infrequently, I would again add, if the disease be in its primary stage.

Most happily, therefore, in my judgment, three plans of treatment have been presented to the medical profession during the past few years for pulmonary phthisis, which, if pertinaciously carried out, may become of untold benefit to the great army of sufferers from this disease. They are in importance as I estimate them: 1, Superalimentation; 2, intra-pulmonary injections: 3, continuous dry inhalations. To the second alone of these methods I shall ask your continued attention this evening, reserving for a future occasion the consideration of the first and third, to which, very properly, I also attach great value.

In beginning what I have to say of intra-pulmonary injections, permit me to quote some remarks taken from a lecture delivered by me at the Bellevue Hospital Medical College, October 28, 1884, and reported in the Philadelphia *Medical Times* of November 15th:

It is in regard to a patient affected with pulmonary phthisis, which had reached the stage of softening at the left apex, and whose left lung, at this region, I injected before my class on the day mentioned. This patient had no laryngeal complication, but suffered from distressing and

[1] Read before the Practitioners' Society, December 5, 1884.

most obstinate cough. To relieve this symptom all ordinary means had been tried, and failed to afford even temporary relief. One week previously I injected ten minims of dilute Lugol's solution into the second left intercostal space, in a vertical line with the left nipple, and to the depth of one and a half inch. The effect of this injection was to lessen his cough very much, and to make, as he stated, his breathing somewhat easier. On October 28th a similar injection was repeated in the same region, and the immediate result was noted. It occasioned very trifling pain, and although the patient coughed a few times immediately after the injection, and expectorated some thick yellow sputa, these were not even tinged with blood. This statement is not always true, as will be remarked further on, since the injections sometimes occasion notable immediate pain and are followed by a few sanguinolent sputa and distressing cough.

In reviewing what pertains to the history of the injection of lung cavities, I am happy to state that one of our countrymen, Professor William Pepper, Provost and Professor of the Theory and Practice of Medicine at the University of Pennsylvania, has hitherto given us the most exhaustive work on this subject, first in the October number of the *American Journal of the Medical Sciences*, for 1874, and later in a communication read before the American Medical Association, and presented to the profession as a reprint from the "Transactions" of that body in 1880.

It seems from a careful perusal of these articles that Dr. Pepper, so far back as 1867, was led by the recognition of the importance which a *low grade of inflammation* had in the development and progress of certain phthisical conditions, to consider the best means of modifying it. Reasoning by analogy, with what is known to be true of inflammatory lesions in external tissues, he ultimately concluded that the injection of the affected pulmonary structures, by means of a small canulated needle, pushed through the intercostal spaces, and charged with some suitable modifying fluid, offered the best guarantee of successful results.

In reviewing the history of ancient operations upon the lungs, it can be shown that while the lung may have been occasionally punctured in the treatment of some ill-defined conditions, usually those resulting from empyema, yet no detailed or exact account comes to us of any methodical treatment of lung cavities. During the middle ages, the history of such treatment is quite as meagre and uncertain.

Baglivi (1696) seems to have been the first author who really pointed out in clear language that an operation might be performed upon lung cavities, by which they could be made to communicate with the outer air, and that the purpose of this should be to apply topical modifying agents to their interior. What was a purely speculative idea to Baglivi, was subsequently actually carried out by Barry (London, 1727). In speaking of this subject, Barry writes most judiciously in regard to the anatomical situation of phthisical cavities, and states the fact that over their site the pleurae are usually adherent; that if the operation be well performed it may be followed by success, and in no event can it be attended with any very great danger, or much contribute to hasten the fate of the sufferer.

Later still, Richter (1805), Herff, Ramadge (1836), and Herbert, a pupil of the former (1845), published cases in which either incision or puncture of supposed pulmonary cavities undoubtedly was performed. Later still, and in spite of a tolerably successful case of incision into an apicial phthisical cavity by Hastings and Storks (*London Medical Gazette*, 1845), the operation fell into disrepute. By many, as Trousseau, Walshe, Copland, and Waldenburg, it is not even mentioned. By Canstatt and Bennett it is only criticised to be condemned, the grounds taken for this condemnation being either that it was directed against a mere localization of a constitutional state, or else that the results met with had been too unsatisfactory to justify further attempts.

Attention, however, was again drawn to this subject by Dr. Wilhelm Kock (*Langenbeck's Archiv. f. Clin. Chir.*, Bd. 15, heft 3, 1873), who showed that injections of dilute solutions of iodine might be made with impunity into the lungs of dogs, and suggested their value in the treatment of certain pulmonary affections in man; and by Mosler (*Berl. Klin. Wochenschr.*, October 27, 1873), of Greifswald, who in two cases introduced a canula into the lung and allowed it to remain, and in a third case made an incision along the upper border of the third rib down almost to the lung, enlarged the cavity by a suitable pair of forceps, and subsequently through the drainage-tube or canula, in all these cases, made repeated injections of different detergent fluids. In no instance did any evil consequences follow, either from the operation or the injections. In the third case, and though the patient died three months after the operation from albuminoid kidneys and spleen and extension of tubercular infiltration into the other lung, the cavity had been favorably modified by the repeated injections of a solution of permanganate of potash or of iodine and carbolic acid. Among the indications which preside prominently in the opening and drainage of lung cavities are: first, to give relative rest to the cavity itself, and thus to promote its contraction and cicatrization. This is done when the cavity is opened and a canula introduced, owing to the fact that as a free exit is given to its contents, cough is immediately lessened in frequency and severity. The second indication, to be carried out by the injection of different detergent fluids through the canula in situ, is evidently the disinfection of the contents of the cavity, at least, such is the idea of Mosler, and of many of those who have followed his lead. Pepper's suggestion is a different one. By *his* system of intra-pulmonary injections, by means of a small canulated needle attached to a Pravaz syringe and filled with a dilute solution of iodine, he does *not* in any way change the relations of the interior of the cavity with the external air. What he proposes to do, and what, indeed, he considers of most importance to effect, is, if possible, the modification of the internal surface of the walls of the cavity, as well as that of the tissues surrounding it. Of course, in those instances where the cavity itself, as well as the change in the surrounding lung tissue, is connected with a marked constitutional condition, as well as with the physical evidence of diffuse pulmonary disease due to tuberculous deposit, local treatment after this manner can scarcely be expected to be of much value. But these are not the only cases. Some there are, where the cavity in the lung is more or less isolated. It is surrounded by a certain amount of fibro-cellular tissue, or cheesy deposit, and the general condition is relatively good while the remaining portions of the lungs are not the seat of any considerable degree of disease. Under these circumstances the cavity itself is a source of constant danger. There is danger of the ulcerative process becoming more extensive, there is risk of profuse hemorrhage, there is great liability of auto-infection, by aspiration of purulent fluid into healthy bronchi of the same or the adjacent tolerably healthy lung. Now, then, what attempt, if such be the case, could be more justifiable than to endeavor, by some method of treatment, to modify this local *state*. And especially is this true if the treatment adopted be free from danger or suffering. By intra-pulmonary injections we should hope to modify the granular surface, the pyogenic membrane, which lines the interior of the pulmonary cavity in such a degree that little by little less pus will be produced, cough and expectoration, in consequence of this, less frequent and abundant, and the cavity tend to contract and cicatrize. Certainly, analogy with what occurs in instances of spontaneous cure will confirm this assumption, since we know that it is only when the walls of the cavity have secreted less abundantly, and the paroxysms of cough have been more moderate and fewer, that the healing process has obviously taken place. Invariably this is connected with

increase of the neighboring fibro-cellular tissue, so that finally the apex of the lung is contracted, the chest-walls become depressed, and ultimately there are complete pleural adhesions over the pulmonary apices.

The method of injection is superior to opening and drainage, as done by Mosler and Storks, first, because by it we are able to introduce any suitable modifying agent directly into contact with any particular portion of the secreting surface of the cavity, or with the tissues surrounding it. It is true, we do not by this method give free exit to the purulent contents, nor, indeed, afford as complete rest to the cavity. In compensation, however, of these advantages, there remains the favorable fact, that a permanent canula and the mechanical irritation caused by its presence is wholly avoided. The method adopted by Dr. Pepper is briefly as follows: A small steel canulated needle, three inches long, attached to a syringe containing twenty-five minims, is employed. Dilute solutions of liq. iodinii comp., at first in the proportion of one part to fifteen parts, later of one part to five parts, were alone used. Pain from puncture was avoided by freezing the surface. The injections were made in the first, second, and third interspaces on a line with the nipple. When the cavities contracted, sometimes the injections were made half an inch inside, or outside this line. The needle was introduced one and a half to two inches, depending somewhat on the emaciation or embonpoint of the patient. The injections were made in the sitting posture, and the patient was ordered to take a long breath and retain it while the injection lasted, which was about thirty seconds. The quantity of fluid injected varied from ℥. iv., the initial quantity, to ℥. xxv. Even the latter quantity never caused any appreciable irritation. The injections were made on an average once a week, and during their continuance the previous general treatment and attention to diet and surroundings were carefully observed. Usually the cavities injected have been superficial ones, and the layer of tissue separating them from the chest-wall quite thin. This layer is made up of a hard fibro-cellular tissue, or indeed of cheesy infiltration. In neither of them do the injections cause any degree of irritation. Indeed, it may be asked whether, in view of the slight reaction and rapid absorption of fluid by the latter, these injections may not be usefully employed, even though no cavity exists. Supposing that a thin layer of healthy lung were interposed between the cavity and the pleura, would the injection prove hurtful or occasion hemorrhage? Judging by clinical experience of acupuncture, chest wounds with pointed instruments, and numerous experiments on animals, the reply should be negative. In one case only, very slight hemorrhage occurred after puncture, and then it was apparently due to the use of the aspirator. Ordinarily, it must be borne in mind, first, that in the superficial layers of the lung there are no large vessels, and second, that many of the vessels existing in healthy lungs become obliterated by the morbid changes, so that there is little or no risk of hemorrhage if the puncture be properly made. The danger of a pneumo-thorax or pleurisy being caused by the puncture is certainly very slight. Usually, as we know, over a chronic circumscribed, superficial, phthisical cavity, the pleuræ are completely adherent, but even if they are not, the amount, if any, of fluid which could pass from the lungs by the way made by the puncture into the pleural cavity would be too small to occasion any injury. It is possible, if attention be not paid to the distribution of the vessels and nerves in the chest-walls, to cause either slight hemorrhage or pain by the puncture. Care should be observed, especially in the portions of the chest outside the nipple-line, to approximate the lower border of the intercostal space, always having in mind the presence of the artery.

In regard to the curative value of this method of treatment it may be said, first, that it unquestionably diminishes considerably the cough, expectoration, and dyspnœa of the patient, as well as the local soreness over the cavity. During the continuance of the injections the patients increase in flesh and strength. Further, reliable clinical evidence shows that the physical signs of a cavity improve during their use. The cavity diminishes in size, and judging by the increased difficulty of making injections after a while, owing to greater development of fibro-cellular tissue, it seems as if the injections occasioned this change. Instead of being irritating these injections are better tolerated when repeated several times. Thus, a severe paroxysm of cough is usually produced by the first injection of a small quantity of a much-diluted fluid. Later, a much larger injection of a stronger solution occasions no cough. Certainly, if by means of intra-pulmonary injections the contents of pulmonary cavities can be disinfected and the walls so modified as to secrete a less quantity of purulent fluid, the secondary evil effects of these cavities, as hectic, constitutional infection, and generalized tuberculosis, will be much less dreaded. Fortunately, later experiences are more than confirmatory of these first well-studied views. There are some differences, however, in later practice which it is well to note. It has been found that at times as much as ℥. i. of dilute Lugol's solution could be injected without producing irritative effects, and that the strength of this solution may be gradually increased until twenty-five per cent. of its full strength is employed, while, with carbolic acid solution, the strength has been between two and three per cent., and the amount from ℥. xx. to ℥. xxx. The latter has been employed only during the time that expectoration was fetid.

In one case of extreme fibroid change in the lungs, and in which repeated hemorrhages occurred in spite of usual remedies, two injections of dilute Monsell's solution were made with great difficulty. In Case No. 11 "the most careful and judicious treatment, including various forms of inhalation, having failed to relieve the terrible paroxysms of cough, which very frequently caused vomiting," intra-pulmonary injections were tried, with excellent results. The expectoration lessened and the paroxysms of cough diminished greatly in frequency and severity. ". . . In consequence of the greatly lessened frequency of vomiting, nutrition improved, and there was some gain in flesh and strength."

This patient subsequently died, and yet "undoubtedly the use of intra-pulmonary injections both prolonged life and greatly increased comfort, while they exerted a beneficial effect on the lesions at the spot to which they were directed."

The injection should be introduced at varying depths, from three-fourths inch to two inches, according to the differences in thickness of the chest-walls and the relatively superficial or deep position of the cavity. Two hundred and ninety-one injections were made in all in seventeen distinct cases very varied in character. Continued observations only prove that dangers from hemorrhage are imaginary; escape of fluid into the pleural cavity does not occur, and frequent passage of a needle through the healthy or diseased lung tissue overlying the cavity causes no irritative disturbance. The paroxysms of cough produced by the first injections can always be allayed by ice dissolved in the mouth, chlorodyne, or denarcotized laudanum taken internally. The pain caused by the puncture rarely requires any treatment. If it does, a moderate hypodermic injection of morphine allays it completely. The most important additional conclusions arrived at seem to be that in diffuse consolidation of a large portion of one lung, intra-pulmonary injections are of no value. Whenever the consolidation is limited to one apex, as it often is in the first stage of pulmonary phthisis, and yet shows no tendency to disappear under usual methods of treatment, but rather to become extensive, intra-pulmonary injections should be carefully tried, with the hope of causing favorable changes in the affected tissues.

Although other modifying liquids may be perhaps employed with advantage, Dr. Pepper's experience is lim-

ited to those I have mentioned. Other experimenters than he have had somewhat different, and not altogether as favorable, results. Thus Sokolowski (*Deutsche Med. Woch.*, No. 29, 1882; *Archives Gén. de Médecine*, vol. i., 1883. pp. 106–108) reports a case of pulmonary phthisis in which there was a cavity on the right side anteriorly. Into this cavity four injections of a one per cent. solution were injected, and two injections of a five per cent. solution of tincture of iodine at different intervals from two to nine days. The operations occasioned cyanosis, cough, dyspnœa, and rise of temperature. Especially was this true when carbolic acid was employed. A short arrest in the march of the morbid process could not fairly be attributed to them (L. Gaillard, Rep).

Fraenkel, on the other hand, reports the case of one patient affected with putrid bronchitis, and in whom he made six injections, using latterly three grammes of a five per cent. watery solution of carbolic acid; not the slightest reaction, not even a single cough, followed this little operation, but there remains the fact that the odor of the sputum was not in the least degree modified (*Glasgow Medical Journal*, 1882). Fraenkel regards the progressive chronic forms of phthisis, particularly in their catarrhal and infiltrative period, as well adapted to the use of antiseptic remedies by means of parenchymatous injections. He hopes in this manner to modify the *parts of lung in which* morbid deposit is made and to increase the tendency of the healthy surrounding parts to throw out a protecting barrier of inflammatory material. In numerous experiments in regard to the effects of the injection of various medicated substances into the lungs of rabbits, Fraenkel noticed very little reaction. Some of the rabbits gained in weight, and physical examination gave no evidence of extension of the pulmonary affection. Slight hemorrhage occurred in the lung and pleura but was usually absorbed. As secondary pathological results, local infiltrations and cellular proliferation in the lung-tissue were noted, but these remained local and showed a tendency toward healing.[1]

The following substances were employed by him; carbolic acid (one to five per cent.); four per cent. watery solution of boracic acid; five per cent. of iodoform in olive oil; two to five per cent. solutions of acetate of alumina. The number of injections was from one to six daily, and the amount of liquid employed was always the same, viz., one gramme. The injections were made during several successive days, or at times a few days interval was left between the injections.

In June, 1884, my own experience in regard to the treatment of phthisical pulmonary cavities by this method was limited to seven patients and nine injections; since June last to the present date, December 5, 1884, I have made twenty additional injections in eleven new patients. The total makes eighteen patients and twenty-nine injections. In my first series of patients the following are the facts remarked subsequently: In five patients I only made one injection in each, in the two others I made two or more injections in each, but I do not now remember the precise number and have lost the record of them. On two occasions I made use of dilute solution of carbolic acid, the other times I employed dilute Lugol's solution. I did not freeze the chest locally on five occasions, to diminish pain; on two occasions I produced local anæsthesia with a spray of rhigolene. On one occasion cough was so severe after the injection as to necessitate a mild opiate internally; on one occasion the pain in the left arm caused by the puncture was very intense. On two occasions the patients complained of pain in one or both shoulders. In two or three instances the patients said they felt better for several days after the injection as regards the cough, expectoration, and general condition. In the other cases no appreciable good effects were noted. In one case there was moderate hæmoptysis after the injection.

[1] London Medical Record, July 15, 1882. Deutsche Medicinische Wochenschrift, No. 4, 1882.

An analysis of my second series of cases shows the following immediate results:

Number of patients, injections, and results, second series.—New York Hospital: total, 4 patients, 6 injections; 2 patients had each 2 injections, 2 patients had each 1 injection. St. Luke's Hospital: total, 5 patients, 11 injections; 1 patient had 4 injections, 3 patients each 2 injections, 1 patient had 1 injection. Charity Hospital: total, 2 patients, 3 injections: 1 patient had 2 injections, 1 patient had 1 injection. In all 11 patients and 20 injections.[1]

The pulmonary condition in these patients was as follows: In two there were cavities, in six there was softening, in two consolidation, in one the physical condition is not stated. On fifteen occasions *no mention* is made of any *pain* immediately following the injection, or it was *distinctly* stated that *no pain* did follow the injection. Inasmuch as every patient injected was questioned closely in regard to this symptom, it is presumable if *mention* of it has been omitted in the histories of the cases that it not *not* occur.

On five occasions considerable pain followed the injection. In one the location of the pain is not mentioned, nor its duration; in one the pain was localized over the region injected, and lasted a few moments. In one, the *pain*, immediately following the injection, was felt "deep down," and lasted during the afternoon and night. It was situated over the seat of puncture, and also extended over the side of the chest where the puncture had been made. In the fourth case the *pain* was felt *intensely* over the upper portion of the scapula of the side injected, and lasted fifteen minutes. In the fifth case the pain was felt in the *left* shoulder, the left being the side injected. The duration and intensity of this pain are not mentioned.

In regard to the *cough* an analysis of my second series of cases shows: *No cough mentioned* on *five occasions; distinct affirmation* that no *immediate* cough occurred on six occasions. On nine occasions there was more or less intense cough following the injection. In seven instances the cough followed the injection immediately, or within a few seconds. In one case cough occurred five minutes after the injection, and in another, twenty minutes afterward. In the seven instances of *instantaneous* cough, its *intensity* is not mentioned in two, but, on this account, was probably slight. In three other instances of immediate cough, it is noted as *slight*, or *moderate*. On two occasions it is referred to as *severe;* on one of these it is stated to have lasted some time, but its precise duration is not written down; on the other no mention is made of the duration. The latter was a case (S——) in whom (November 1st). after the first injection, the cough began in five minutes from the time of injection, and lasted during the remainder of the afternoon, requiring the use of anodynes that night to give him relief. This man had, prior to his injections, suffered from the most distressing cough, that I had endeavored in every way, although unsuccessfully, to allay. His cough, subsequently to the two injections, was perhaps somewhat worse for a day or two, but later was neither better nor worse than it was previous to the injections. The patient himself had, evidently, a very irritable, querulous disposition. In the instance in which the cough began twenty minutes after the injection, it was not very severe. In two cases *moderate* immediate cough lasted about ten minutes, and in one of these, after the paroxysm, the patient stated that he *felt easier*, and his lungs were *more comfortable*. On nine occasions there was *not* the slightest hæmoptysis after the injection. On seven occasions *no mention* is made of hæmoptysis, and presumably it did not occur. On one occasion there was slight *external* bleeding at the site of puncture. In two cases there was some blood-streaked sputa, and in one case only the hæmoptysis was at all notable, and stopped spontaneously at the end of twenty minutes.

[1] Since this report was written I have made three more injections.

Among the other *immediate* results of the injection we should note the following: In one instance the patient had an attack of syncope which lasted a few moments, and from which he recovered easily. In one case there was complaint of an exhausted feeling. On three occasions the patient complained of painful sensations in the throat —on one it was a feeling of constriction, on another it was one of strangulation, on a third it was a burning sensation. On the two last occasions there was considerable dyspnœa, and the patient tasted, or spat up, *iodine*.

Among the near consequences of the injections we should remark the remarkable one which occurred to the patient J——, who complained, about three hours after the injection, of severe pain in coughing and swallowing, and it was found that there was interstitial emphysema over both sides of the neck and over the pectoralis major muscle of the left side. The emphysema lasted four days, disappearing little by little. At one time the pain in swallowing was so considerable that the house physician felt called upon to administer a small dose of morphine with the hypodermic syringe.

On one occasion, the day following the injection, the temperature curve showed a rise of 1½°. Ten days previous to the injection there had been an equal rise of temperature, but in the interim the temperature had been falling. It was inferred that the injection had caused the augmented temperature, particularly as this symptom was accompanied by localized pain over the chest anteriorly, which was quite intense and lasted three days without diminution (dry pleurisy?).

In regard to the effects of the injections after several days had elapsed, the following were noted: In six instances the patients were *certainly* benefited with respect to their cough and breathing; the cough was less frequent and intense and the breathing notably easier; sleep was better, also, by reason of improvement in the cough. In one case, localized pain, from which the patient had suffered much previously, was diminished. In three cases the expectoration was considerably less, and in one of these the sputa were also favorably modified in appearance. In two cases there was no benefit to cough or other symptoms. In one case the localized pain was apparently increased by the injections. In one case bronchial breathing diminished in intensity, but the râles became more numerous.

In order to determine the precise regions of the chest in which injections could be made with safety, or with greatest advantage, long needles were introduced through the lungs in different interspaces of the thorax, anteriorly, posteriorly, and laterally. These experiments were made by Dr. Satterthwaite and myself in the post-mortem room at St. Luke's Hospital, and in the presence of the house staff. It was determined: A. That the axillary region, high up in the first, second, and third interspaces, with the arm elevated at a right angle to the chest, was the best region from which to make intra-pulmonary injections into apicial cavities. This was believed to be true, first, because the penetration of the needle need not be so deep as elsewhere; second, because the apex cavity was more directly and easily penetrated, and the danger of injury to any important blood-vessel wholly avoided. B. *Posteriorly* intra-pulmonary apicial injections could be made only with great difficulty, risk, and uncertainty, owing to the narrowness of the intercostal spaces, the depth of tissue through which it was necessary to plunge the canulated needle, and the impossibility always of avoiding the puncture of the heart, or great vessels. C. *Anteriorly*, punctures could be made with ease and safety in the first, second, and third interspaces, on a vertical line with or outside of the nipple, but not *inside* of this line. If this were done, it seemed possible, and even probable, unless the limit were only passed by a very short distance, that the needle would almost inevitably be thrust into the heart, pericardium, or one of the great vessels of the chest. The results here reported are, I regret to add, but the remembrance of what was obtained. Careful notes were jotted down by one of my assistants at the time of our experiments, but these were afterward mislaid and lost.

My cases, imperfect though they are, corroborate Pepper's testimony that intra-pulmonary injections in phthisis, when properly made, are not dangerous. They also show that in many cases we may fairly hope that they will relieve symptoms. Among those which have been sensibly ameliorated are cough, dyspnœa, the quantity and character of the sputa. Still there are probably certain cases in which no relief will be obtained, and with our actual knowledge the cough may perhaps be augmented in intensity and frequency during a few days. Further, injections may occasion slight accidents—none of them grave, fortunately. These are slight hæmoptysis, syncope, choking sensations in the throat, localized pain, limited pleuritis, emphysema, rise of temperature. Some of them last but a few days, and afterward disappear entirely; others are mere temporary occurrences, and only last a very short time, and do not return.

It will be remarked that I have not limited my injections to apices where lung cavities were unquestionably present, but have considered it indicated to inject *consolidated tissue* or that which had already reached the stage of softening. It has been asked me what I expected to obtain by such injections, and my reply has been *resorption* of inflammatory processes, or of the results of the same. Do we not obtain very remarkable results, at times, from the injection of infiltrated tissue *in and about* lymphatic ganglia in the neck and elsewhere? Have we not often seen *fibrous goitre* diminish very much in size from intra-parenchymatous injections of iodine? That is true, you reply, but a phthisical lung is a process of very different order, and in no mauner resembles the instances you cite. Pardon me, but this is not correct. Apart from the latest theory of the parasitic origin of tubercular disease of the lung, there is still a *fair basis* for the assumption that many of the local changes we encounter in phthisical lesions are strictly inflammatory in type, and may, and should be treated in such a manner as to bring about profound changes in their growth and development. As a consequence of these changes, resorption may and probably will take place in a certain length of time. Whether it be essential for the apices to become softened before resorption can take place, after intra-pulmonary injections into consolidated tissue, I am not prepared altogether to affirm. I think it *probable* where the infiltration is in great part due to cheesy changes in the pulmonary tissue. When, on the contrary, the local pulmonary changes are largely fibroid in character, I am not unwilling to believe that slow, continuous resorption of this adventitious growth of tissue may take place without of necessity passing through any stage of softening. I do not presume that a weak solution of iodine, such as I have hitherto employed, could have any great effect in preventing the growth of bacilli. Still it is not established what real tolerance a *diseased lung possesses*, and who knows what strength and kind of solutions we may yet be able with almost absolute impunity to inject into its structure. Among these fluids, some may be found that will destroy the main foci of bacilli, and help largely, with the other means indicated already, as strong adjuvants of this treatment, to bring about complete cures.

Even should we ultimately fail in this, to some, Eutopian scheme, is it not, even now, proven that when other therapeutic measures fail to alleviate *cough, dyspnœa, profuse expectoration*, that *all these* symptoms may, at times, be notably diminished by the use of intra-pulmonary injections. In regard to their effects on lung cavities, I am of opinion that, when persisted in, they will disinfect their contents; they will also modify and diminish the secretions from the walls of these cavities; they will tend to effect cicatrization and contraction of these spaces, usually filled with a material which is a constant source of peril to the patient. I have not been convinced, as yet, of the advantage to the patient when bearer of a

phthisical cavity, of a free opening through the chest-wall and complete drainage of it. But this is a very different matter from the little operation we have considered, which may be repeated again and again without risk or shock to the patient, and which promises well to many sufferers if they have the faith to hold out until the good results are acquired. This leads me to make a statement which it is well to recognize. Many patients will object to the treatment through fear. This may usually be quieted if the physician be not interfered with. If, unfortunately, there should be any unwise interference on the part of a short-sighted but kindly layman, the patients will refuse their consent to a continuance of treatment. This difficulty time will overcome when intra-pulmonary injections have become, as I believe they will, a well-recognized and useful addition to our means of battling with that dread destroyer, phthisis pulmonalis.

I have endeavored, gentlemen, in this brief and imperfect manner, to give you a slight *aperçu* of what I esteem to be a real advance in the treatment of pulmonary consumption. We all know, as I have pointed out in the beginning of my paper, what treatment by the old methods means for the vast number of unfortunate beings who crowd our city dispensaries and hospitals. With the three late methods presented to the profession, viz.; super-alimentation, continuous dry inhalations, intra-pulmonary injections, many patients will yet be saved, who, with cod-liver oil and the hypophosphites alone, or added to other resources usually employed, would most certainly die. Nothing prevents us from using all previous means to help our phthisical sufferers, but I would also make a very urgent p'ea for those I have just mentioned.

A CRIME PECULIAR TO A PHYSICIAN.

By HENRY A. RILEY, Esq.,

NEW YORK.

One of the most disgraceful crimes which a physician, in his professional capacity, can commit, is the taking advantage of the confidence of a female patient when advice is sought for troubles peculiar to the sex, and by force or fraud making a criminal assault upon her for the purpose of sexual connection. An act of this kind, so peculiarly dishonorable to the physician, and so unfortunate in its possible results to the patient, is not impossible when one considers the passions of men, but it is a matter for congratulation that charges of this sort are so comparatively rare. The general standard of morality and professional honor is so high that the law-books contain few cases on the subject. There are some, however, and it may be well to call attention to several of them. It may be said, in general, that the crime is universally regarded as a most serious one, and in most of the States is declared to be a rape. There has been some discussion in a few of the cases as to the question whether the submission of the female to the act did not lower the grade of the crime, and either make it merely an assault, or else warrant the conclusion that there was consent on her part, and thus take it entirely out of the category of crimes. This view is not generally taken, however, and at the present time perhaps only in those States where the statute requires the element of force to constitute the crime of rape. An instance of this view of the subject will be referred to later.

One of the first cases on the question is Regina's case, an English one, occurring in 1850, and reported in 1 Denison's Crown Cases, 580. Here the patient was a young girl, only fourteen years of age, who had been placed under the physician's care in consequence of illness arising from suppressed menstruation. The treatment adopted did not seem to accomplish the result, and, as the evidence states, he told her that he must try some further means, he then took hold of her and had sexual connection, no resistance being made by her, believing, as she stated, that she was submitting to medical treatment for the ailment under which she labored. Upon the trial, the magistrate said that she was of the age to consent, and if she did, the defendant ought to be acquitted, but if she was ignorant of the nature of the act, and thought it was part of the proper medical treatment, it amounted to an assault.

The jury found the physician guilty, and he was sentenced to eighteen months' imprisonment. The case was then appealed, and the propriety of the conviction came up for review before a higher court, where it was affirmed. The Court said: "The finding of the jury is clear. They are told that if they think she consented to the carnal connection they must acquit, that the girl was competent to consent, and that it is a question for them whether she did or no. The girl is fourteen years of age. She might at that age be ignorant of the nature of the act morally as well as physically, and of its possible consequences. It is said that as she made no resistance she must be viewed as a consenting party. That is a fallacy. . . . The prisoner disarmed her by fraud. She acquiesced under a misrepresentation that what he was doing was with a view to cure and that only, whereas it was solely to gratify the passion of the prisoner. How does this differ from a case of total deception? She consented to one thing, he did another materially different."

In this case the prisoner's counsel suggested that perhaps the act of sexual connection was in reality part of the medical treatment of the case, and that it should have been left to the jury to decide this point. The court with some emphasis said in regard to this defence that it certainly was not left to the jury and need not have been. "The notion that a medical man might lawfully adopt such a mode of treatment is not to be tolerated in a court of justice."

In the case of Regina *vs.* Stanton, 1 C. and K., 415, another English case, there was an indictment for an assault with intent to commit a rape, the physician having obtained access to the person of the woman under pretence of administering an injection, and commenced to have carnal connection with her, when she discovering it got up and ran out of the room. Upon this state of facts a conviction was had for the assault.

In Queen *vs.* Flattery, 2 Q. B. D., 410, decided in 1877, the charge was that of rape, and the defendant was convicted under the following circumstances: The prosecutrix, a girl of nineteen, was "subject to fits," and she and her mother consulted the defendant in regard to her case. He made an examination of her person and advised that a surgical operation be performed, and under the pretence of performing it had carnal connection with her. The Court said in this case: "It is plain that the girl only submitted to the defendant's touching her person in consequence of the fraud and false pretences of the prisoner, and the only thing she consented to was the performance of the surgical operation. Up to the time when she and the prisoner went into the room alone, it is clearly found that the only thing contemplated, either by the girl or her mother, was the operation which had been advised; sexual connection was never thought of by either of them. And after she was in the room alone with the prisoner, what the case expressly states is that the girl made but feeble resistance, believing that she was being treated medically, and that what was taking place was a surgical operation and nothing else. It is said, however, that having regard to the age of the prosecutrix, she must have known the nature of sexual connection. I know of no ground for such a proposition. And even if she had such knowledge she might suppose that penetration was being effected with the hand or with an instrument."

The case of Santiago Don Moran *vs.* The People, 25 Mich., 356, tried in 1872, is an apparent exception to the general rule that submission under the idea that the act is a part of the medical treatment constitutes a rape, but here the decision is based upon the words of the statute, which expressly say that force is necessary to create the crime

of rape, and the court would not stretch the words of the statute so as to cover the case.

The facts of this case were quite peculiar. The defendant was a physician practising in the city of Detroit, and a girl, sixteen years of age, was brought to him to be treated for consumption. He made an examination and then informed her that the "whites" had collected in her stomach, that she was ulcerated, that her uterus was inverted, that to save her life it would be necessary to enlarge the "parts" so that the "whites" might pass off; to break the ulcers and to turn the uterus; that he could do this with instruments, but the operation would probably kill her; that the only way would be for him to have carnal connection with her. When she objected, he told her that it was what he did to all women who came to be treated by him. He said he had told her father that it would be necessary, and he had authorized the defendant to have connection with his daughter. Upon such representations as these she allowed him to have intercourse with her.

When these facts became known the physician was indicted for rape, and convicted, but upon an appeal this verdict was reversed, and a new trial granted, on the ground that no force was used. The Court said: "Upon abstract principles of right and wrong a sexual connection obtained by falsely and fraudulently personating the husband of a woman or by a physician fraudulently enticing a female patient to believe such connection essential to a course of medical treatment must be considered nearly, if not quite, as criminal and prejudicial to society as when obtained by force or any apprehension of violence, and it might, and in my opinion would be, judicious for the Legislature to make some provision for punishment in cases of this kind, but it is not for the judiciary to legislate by straining the existing criminal law to bring such cases within it."

The latest case on the general subject is one just tried in Indiana, and found in the last volume of Reports (Pomeroy *vs.* State, 94 Ind., 96). Here it appeared that the patient was suffering from a disease of the womb, and the physician, while examining her person, had sexual connection with her. He was tried for the offence and found guilty of rape. The Court said: "The evidence tends to show that the appellant, as a physician, informed Rebecca and her mother that the former was suffering from a terrible womb disease and was losing her mind. If the jury believed, as they might well have done from the evidence, that the appellant as physician obtained possession and control of Rebecca's person under her mother's command, for the purpose of making a further examination of her alleged disease of the womb, and not for the purpose of sexual intercourse, and that she never in fact gave her consent, through fraud or otherwise, to the sexual connection, then it seems to us that the appellant was lawfully convicted of the crime of rape." The sentence was therefore affirmed.

These cases will go strongly to show the comparative infrequency of the crime, and also that the courts in general regard it as belonging to the highest grade of crimes of that nature, and punish it severely whenever the guilt of the physician is fairly made out.

THE PROPER CHEMICAL TERM FOR HYDRO-CHLORATE OF COCAINE.—The *Drug News* contains an elaborate article upon this subject, concerning which also Dr. John North, of Keokuk, Ia., sends us a learned letter. The question is too purely a chemical one for our columns. Dr. North contends that the present term is correct. "The salt," he says, "cannot be called a chloride because it has a linking element and is not a binary compound. It cannot be called a chlor*ate* because the term chlorate is used where the linking agent is oxygen. We call it *hydro*chlor*ate* because it has a linking element, and the linking element is hydrogen."

MULTIPLE ŒDEMATOUS SWELLINGS OF THE SKIN, DUE TO RHEUMATIC VASO-MOTOR AFFECTION.

BY A. SEIBERT, M.D.,

PHYSICIAN TO THE DEPARTMENT FOR DISEASES OF CHILDREN AT THE GERMAN DISPENSARY, NEW YORK.

ON July 2, 1884, a gentleman, aged forty, came to my office and related that about two hours ago he had jumped from the driver's seat of a high wagon, but that he had in no way injured himself by this leap. One hour later, while urinating, the patient noticed a considerable swelling of his penis, therewith no pain or other complaint. On examination the following condition was found:

Strongly built, well-nourished man, with abundant adipose tissue. Had drank considerable quantities of beer all his lifetime, and had been a very moderate eater for the last few years. Furred tongue; quick pulse, but no elevation of temperature. Lungs, heart, liver, and spleen normal. No hernia; no swollen glands; no stricture. The urine is clear and contains no albumen.

The prepuce is in a state of considerable œdematous swelling, while no apparent inflammatory cause exists. No paraphimosis. The swelling is evenly distributed in the prepuce. The upper covering of the penis is not involved.

Directions: Rest in bed; ice-bag on the perineum; iodide of potassium.

July 3d.—The œdema has nearly disappeared.

July 4th.—The swelling is all gone; patient is allowed to get up. Hardly an hour after the patient's rising the swelling appears again. After resting forty-eight hours the œdema again subsides, but only to appear again on the man getting up from his bed. Thus three times the disappearance of this phenomenon follows a rest of two days' duration. From July 11th (being the tenth day of ailment) the œdema does not disappear any more, in spite of continued rest.

July 13th.—A large, well-marked œdema appears on the right side of the abdomen, extending from the vertebral column forward to about the mammillary line, upward to the twelfth rib, and downward to the crista ilei. The skin in this region is very much swollen and tightened, showing a reddish-bluish appearance which is mostly marked in the centre of the patch. No heat in the part whatsoever. On pressure the characteristic dent for œdema is left for quite some time. On percussion the sound over this region is absolutely dull (as was afterward learned, owing to the enormous swelling of the integuments of the skin). Within the next few days œdema of the right ankle region and of the right upper leg appeared, the œdema of the prepuce meanwhile growing in intensity and spreading over the testicles. This state of things remained the same to the beginning of the fourth week, when a light œdema of the left ankle-joint region and of that part of the back corresponding to the affected portion of the right side, appeared. This last œdema does not extend forward above the axillary line, and is not so well marked as that of the other side, but shows the same reddish-bluish appearance.

Meanwhile, the patches of œdema on the right half of the body had grown to an enormous extent, so as to make it appear decidedly larger than the left side. The swelling in the skin of the back and abdomen now extended upward to the mammilla, downward to the knee, covering the gluteal region as well as the surface of the whole thigh. The skin of both lower extremities below the knee (with the exception of the ankle-joints) was not swollen in the least. The prepuce had grown to an enormous size, the covering of the testicles being by far less swollen. The right side of the face also showed slight œdematous swelling. There was no ascites present.

During these five weeks the patient had no fever and no pains at any time. His appetite was fair, his digestion normal, and he never was constipated. The exami-

nations of the urine, though daily repeated, revealed no albumen, no sugar, and no abnormal quantities. The microscopic tests proved fruitless. The man was patient, and his humor as good as ever. His sleep was sound and uninterrupted. The only abnormal sign outside of the swellings consisted in an acceleration of the heart's action, for during the full course of this disease the pulse beat ninety-six times per minute. The treatment employed consisted in absolute rest in bed, good nourishment, and of drugs: iodide of potassium, large doses of quinine, digitalis, ergot, and calomel. The result of this treatment was entirely negative, so that not the slightest symptoms mentioned above (as, for example, the quick pulse) changed or disappeared.

Before reporting the further history of this case we might as well try and diagnosticate. At the end of the second week, when the prepuce and a circumscript portion of the back and abdominal wall of the right side, together with the skin covering the right ankle-joint were swollen, it appeared rational to refer these isolated, œdematous swellings of skin to some pressure most likely exercised upon that region of the abdominal cavity partly transversed by the internal iliac artery. The dull sound on percussion, the unconquerable difficulty to palpation, together with the peculiar mode of appearing and disappearing in the beginning of this affection, as well as the location of the most extensive swelling, gave great probability to the idea of some malignant tumor within the abdomen. The right kidney and the abdominal lymphatic glands might have been thought of. True that no cachexia existed, and no abnormal substances were noticeable in the urine, but both may be wanting for a long time, and still the kidney, for example, may be degenerated totally into cancerous tissue, as I lately was able to demonstrate in the case of a child aged ten months (*Jahrbuch für Kinderheilk.*, vol. xxi., Heft 3. Leipzig, 1884).

Later, when the right thigh, the covering of the testicles, and the dorsum of the right foot were also implicated, ascending thrombosis might have covered the picture thus presented, provided the beginning and the course of this case were not known. This assumption, therefore, could not hold—1. Because the œdema had appeared at the prepuce, the abdomen, and the back, long before the swelling over the extremity; and 2. Because the œdematous places in the skin were not located next to each other and following the ascending course of one or more veins, but presented isolated patches surrounded by normal skin. Thus the preputial and abdominal swellings were isolated from each other and from that of the thigh, that of the foot from the swollen upper leg by the not swollen lower leg. 3. No cause for a possible thrombosis could be discovered.

The last resource for diagnosis in this case was presented by the central nervous system. Syphilis was positively denied, and the want of swollen glands, as well as the negative result of continued large doses of iodide of potassium, verified this statement. Though during the progress of this case I was continually pressed to assume some affection of the vaso-motor nerves, either peripheric or central, I freely confess that a diagnosis of this kind did not satisfy me at that time, partly because the text-books did not speak of such disease, and partly because I could not find one case similar to this in literature, though the experience of Professor Jacobi, who saw the patient in about the third week with me, was at my command.

At the end of the fifth week, when the symptoms described above were at their height, the patient one morning complained of soreness in the joints of the right big toe. Redness and swelling were wanting. As I had treated the man about a year previous for arthritis rheumatica, I suspected that a new attack of this malady was threatening, and therefore ordered salicylate of soda, one gramme to be used every hour. On visiting the patient the next day I not only found that the pain in the toe had disappeared, but also that the œdema of the skin had decreased in intensity to a remarkable degree. All œdematous patches were less swollen; in the face only a slight swelling below the eyelid remained; the left foot and the left side of the back had completely lost their œdema, while the great swelling of the prepuce, the right side of the abdomen and back, as well as the right thigh, had diminished considerably.

To be brief about it, the treatment with salicylic soda was continued, and within six days after the beginning of this treatment the patient was discharged cured. The œdematous swellings disappeared in the same order in which they made their appearance, and according to their intensity, those least marked first and those most developed last.

Ranvier (in his work on "Experimental Œdema," Paris, 1869) proved that it did not suffice to ligate a vein; for example, the largest one of an extremity, to produce œdema, but that the vaso-motor innervation of the district supplied by this vessel had to be interrupted by either ligation or section. He even proved that in these experiments the œdema was due solely and alone to vaso-motor disturbance, for after severing the root of the ischiatic nerve within the spinal channel (in which locality the filaments of the sympathetic do not accompany the ischiatic so numerously as in the latter's course outside of this channel) the expected œdema, before easily produced, did not appear.

Boddart ("Notes sur la pathogénie du goitre exophthalmique," 1872) reports a local œdema of the neck in consequence of the ligation of filaments of the sympathetic supplying the head.

Mitchell ("Des lesions des nerfs et de leurs consequences," Traduction, Paris, 1874) has seen œdema appear in one hundred and six cases of neuralgia, either before or during the attacks.

Schwimmer (in his monograph, "Die Neuropathischen Dermatonosen," 1883), while speaking of œdema, relates a case of carcinoma of the mediastinum, in the course of which attacks of intense neuralgia of the right face and chest appeared with œdema. On suppressing the pain with morphia the œdema vanished with it, to again appear when pain set in.

C. Gerhardt ("Ueber einige Angioneurosen," Saml. klin. Vortraege, Volkmann, 1881) not only makes mention of one-sided vaso-motor facial paralysis, but also as counterpart of cutaneous gangrene consequent upon poisoning by secale cornutum, to show the importance of the vaso motor nerves.

Eulenberg reports a case of Mauthner (*Deutsch. Archiv f. klin. Med.*, ii., 2) where a young chlorotic girl was frequently attacked by contractions of the cutaneous vessels of the hands and feet, lasting several hours and followed by reactionary paralysis of the vaso-motors, with œdema. These attacks disappeared together with the chlorosis.

Negel (*Progrès Medical*, 1884, p. 846) reports the case of a woman, forty years old, who was similarly afflicted, the contractions of blood-vessels setting in regularly upon the patient's washing her hands with cold water. The pains during the attacks in the afflicted parts were intense in this case, redness and swelling accompanying them. Duration about five minutes. Treatment with salicylic acid internally removed the disposition for these attacks quickly and thoroughly.

Symmetric gangrene, first spoken of in detail by Raynaud and lately by Weiss (*Wien. Klinik.*, Hft. x., 1882), also belongs in the class of vaso-motor disturbances.

These examples necessarily prove the existence of vaso-motor nerves and their liability to disease. The affections of these nerves seem to produce two distinct conditions of the organs they innervate: spasmodic contraction and paralytic expansion of the blood-vessels.

In studying the history of the above cases the following ideas occur to me: The diseases of the vaso-motor nerves can be classified into

1. Local affections. The cases of Mitchell, Schwimmer, and Negel are to be looked upon as neuralgic affections of cutaneous nerves in which, through various causes, an irritation not alone causes paroxysms of pain in the one, but also contractions of blood-vessels, by means of the vaso-motor fibres. The attacks of neuralgia, *i.e.*, the irritation, keeping up longer than the spasmodic contraction of the muscular fibres of the arteries can hold on—paralytic relaxation consequent upon this exhaustion sets in, and thus, even while neuralgia continues, œdema appears.

2. Vaso-motor affections of central origin. Symmetric gangrene, cutaneous gangrene, produced by poisoning with ergot (Gerhardt, *loc. cit.*), and the case of Mauthner are to be classified under this heading. The very fact that in symmetric gangrene the affection manifests itself on both sides of the body, equally distributed, leaves no doubt as to the central origin. In giving ergot we well know that the action of the drug is not a local, but a general one, therefore caused by the latter acting upon that nerve-centre, controlling the contraction of the muscle-fibres of arteries. In the case of Mauthner the existing chlorosis proved to be the cause of the irritability of the vaso-motors.

Our case differs in various important points from those just related.

1. There was no pain at all, which proves that no local inflammatory irritant was present (as in those cases connected with neuralgia), and also that no contraction of arteries preceded their dilatation (as in symmetric gangrene, etc.). As therefore only the vaso-motor nerves could have been affected, and as this affection was manifested only by paralytic dilatation of blood vessels producing œdema, it follows that the irritant most likely was located centrally.

2. The large surface covered by the œdema is unusual. This as well as the peculiar mode of appearing (at first all on one side, then on the same points of the other side, and then in isolated patches), seems to point toward central lesion.

3. The long duration of the swellings, their gradual development, and their steady increase in intensity and circumference—showing that the cause not alone persisted in remaining, but also in growing more and more manifest.

4. The abnormal rapid action of the heart, always remaining unaltered and not in the least influenced by large doses of digitalis (a symptom which Gerhardt, *loc. cit.*, pronounces pathognostic for paralysis of the vagus), presents an interesting complication of diagnostic value, also pointing to central disturbance. The centre for retarding the action of the heart, as well as the main one for the vaso-motor nerves, is located in the medulla. Many of the vaso-motors partly run with spinal, others with sympathetic nerves, all those for the lower half of the trunk and the lower extremities being intermingled with communicating fibres of the sympathetic.

Keeping these facts in mind we have two alternatives left, either (1) the phenomena in this case were due to some change (rheumatic?) in or near the medulla, depressing the tonus of the exciting centre for contraction of the cutaneous arteries and at the same time producing partial paralysis of the vagus (with subsequent abnormal heart action); or (2) a rheumatic affection of parts of the sympathetic, producing by means of contact with trunk-fibres of the vaso-motors at the same point or points depressed innervation of the latter. The choice between these two explanations is left to the reader.

One of the Large Hearts.—Dr. F. A. Rice, of Bridgeport, Conn., writes: "A cabinet-maker, aged forty-nine, had an attack of acute inflammatory rheumatism at the age of twenty. He subsequently suffered from symptoms of mitral disease, and eventually died therefrom. On autopsy the heart, emptied of blood, was found to weigh exactly forty-four ounces. The cavities would hold from eight to ten ounces."

CONTRIBUTION TO THE PATHOLOGY OF NOMA.

By WILLARD H. MORSE, M.D.,

NEW YORK.

As the result of an extended study of the subject, it was my pleasure some seven or eight years ago to give, through the Louisville *Medical News*, some notes on noma, in which I laid down the expression of an opinion that it was quite possible that in cases of the disease moving bodies might be observed in the blood during life. Much to my alarm and surprise, my opinion was severely criticised, and I was most solemnly assured through the columns of our leading medical journals that such a thing was quite an impossibility. The cold water thrown on the idea was of such conclusive frigidity that it was not until lately that I presumed to seek for substantiation of the fact. As the outcome of this further observation I have to report the following illustrative and interesting case:

The patient was a little boy, eleven years of age, the child of healthy German parents of faultless family history, and himself a lad of good constitution and excellent hygienic surroundings. On or about October 13th the mother came to my office with the patient, who was complaining of a pain in the right side of his face. There was apparent evidence of neuralgia, the inception of the difficulty having been remarkably sudden. There was, however, no sign of dead teeth in the jaws, and no history of exposure to cold; and though the ambiguous nature of the symptoms left much to exclude and more to admit, I found no difficulty in diagnosing noma. The disease had commenced three days before, and there were absolutely no other symptoms than the pain, which was constant, lancinating, and intense. Prostration had begun, and became very great before the week had passed. Great tenderness of the cheek supervened, and sloughing took place. A copious hemorrhage ensued on the afternoon of the 21st, and on the following day I found the cheek completely perforated. As a matter of course, the inferior maxilla became necrosed, and more hemorrhage occurred. On the 29th the child died. The autopsy showed a very extensive and complete necrosis of both the superior and inferior maxillæ of the affected side, as well as a general destruction of the tissues surrounding the right cheek and right side of the tongue.

The microscopic examinations of the blood were frequent and thorough during the time that the patient was in my charge. Previous to the primary hemorrhage, there had been a very notable excess of the white elements, the colorless corpuscles numbering one to three of the red corpuscles, and existing in a broken and ragged condition. Examination by a high power revealed a large number of minute colorless bodies, highly refractile and of apparent crystalline consistency, in active and irregular movement. At several subsequent times the number of these bodies varied, but their motility never showed change. After the occurrence of hemorrhage and fall of temperature they were found in diminished numbers, but when the temperature was much accelerated they were in greater abundance. When numerous they were always found in zoöglœate groups. I made a careful series of experiments with reagents, and watched the responses of the degenerate white corpuscles with much interest. I regret that the report of these experiments has been accidentally destroyed, and I can only refer to them in a general way. By the way of summary: they were stimulated by solutions of potash and sulphuric acid, and were arrested by solutions of quinia sulphas and carbolic acid. The corpuscles averaged a size equal to one-tenth of that of a red corpuscle.

Much to my delight, I found on the second day before death the presence of a goodly number of ordinary bacteria in the blood with the white corpuscles. They were also observed in the urine, and were seen in

the fæces. The matter discharged from the wound contained them in a mass in abundance.

The autopsy was held twenty-one hours after death, and on that occasion I obtained for experimental purposes some blood from the right auricle, fluid from the seat of the noma, and specimens of necrosed osseous tissue. The fluids were kept hermetically sealed in capillary tubes, and were carefully preserved. My subsequent investigations were undertaken with the purpose of studying the infective character of both the blood and secretions, and were performed in the week that followed the termination of the case.

1. A young rabbit, inoculated with auricular blood, survived the operation three days. An examination of its fresh blood showed a vast number of the translucent corpuscles. 2. A second rabbit, similarly treated, died on the following day. On post-mortem examination there was distinct peritonitis, and the bases of both lungs were consolidated. The peritoneal exudation showed vast numbers of the white corpuscles, resembling exactly those found in the blood. 3. A young rat, killed twelve hours after inoculation, manifested an abundance of the motile bodies in the warm-drawn blood. 4. The fluid from the wound was injected into the veins of a rabbit and two cats. In each case the animals died in a few hours, and though there was peritonitis, there was no presence of the white bodies in their blood.

In no case were bacteria propagated. No evidence of the existence of these organisms was given, though the child died with its blood swarming with them. The white globules, when reproduced, were of the same character as primarily. I also deduced that inoculation of the fluids derived from the seat of the noma produced no alteration of the blood, though causing peritonitis, while inoculation of the diseased blood induced septicæmic change, with the manifestation in the blood of the characteristic motile corpuscles observable during the course of the original disease.

Clinical Department.

A GOITRE SUCCESSFULLY TREATED WITH IODINE INTERNALLY AND BY INJECTIONS.

Dr. G. W. McCaskey, of Fort Wayne, Ind., was consulted on July 2, 1884, by a young woman, unmarried, aged twenty-five, on account of a small goitre. It measured three and one-half inches from side to side and from one and one-half to two and one-half inches vertically, being larger on the right side. It was firm and non-cystic.

The treatment consisted of Lugol's solution, gtt. vj., three times per day. From once to twice each week the tumor was injected with tr. iodine, gtt. iv.–vj., the length of time between injections depending upon the persistence of the swelling. About twice each week the galvanic current (twelve cells), with the cathode over the tumor, was used for twenty to thirty minutes.

The result of three months' treatment was to cause the entire disappearance of the enlargement upon the left side, leaving what seemed to be a slight thickening and induration of the tissues on the right side. This thickening had remained up to the date of last examination, some two months after the cessation of active treatment. The neck was reduced in size from thirteen and one-half to eleven inches.

The patient lost fifteen pounds in weight, about one-seventh her entire weight. When the debility became very marked, Lugol's solution was suspended for a week. This was necessary twice during the treatment. When the treatment was discontinued the patient regained her original weight in less than a month, without any recurrence of the tumor.

The troublesome dysphonia, which led the patient to consult me disappeared in about one month after the commencement of treatment. The pressure seemed to be removed from the larynx before any obvious diminution had occurred in the bulk of the tumor.

TYPHOID FEVER WITH PERFORATION FOLLOWED BY COMPLETE RECOVERY—NOTES ON TREATMENT.

The very rare occurrence of recovery after perforation of the bowel in typhoid fever lends interest to the following case, carefully recorded by Dr. Lloyd Norris Horwitz, of Philadelphia, late Resident Physician to the Philadelphia Almshouse Hospital :

The patient, a man aged thirty-four, was brought to the hospital on about the eighth day of the fever. He showed the characteristic symptoms : Rose-colored eruption, loose bowels, temperature 104° to 105°, low delirium. On about the twelfth day of the fever he was suddenly seized with a violent chill, followed by great prostration : Feeble intermittent pulse, shallow respiration, contracted pupils, temperature 105⅗° F. Three hours later a second chill occurred less violent. It was preceded by a bloody stool. Unmistakable symptoms of peritonitis then set in : Tender, tense, tympanitic abdomen ; small wiry pulse ; shallow, frequent respirations ; temperature 106⅘° F. Another bloody stool was passed.

"One of the peculiar features of the case," writes Dr. Horwitz, "was the total disappearance of the eruption after peritonitis was fully established, nor did it again recur until all symptoms of peritoneal inflammation had entirely passed away.

"This anomalous symptom, if symptom it may be called, has, to the writer's knowledge, been only observed in one other instance, and that was in a patient of one of his colleagues at the same hospital in which his patient was confined. The delirium, also, which had up to the time of peritoneal involvement been well marked, lessened greatly, and oftentimes during the subsequent thirty-six hours, the intellect of the patient was quite clear, thus forming a striking contrast to his previous mental hebetude and hallucinations."

The symptoms next day increased. The abdominal pain was very great, especially over the upper left iliac region. On the second evening after the complication began, symptoms of profound collapse developed.

"Under the use of tablespoonful doses of brandy frequently repeated, along with the employment of the hypodermic injection of ammonia, with mustard plasters and warmth to the extremities, these ominous symptoms gradually subsided, the heart's action slowly gaining in strength, and the respirations increasing in frequency and depth.

"The following morning all of the very grave symptoms of the previous night had subsided, and the patient, although weaker, was pretty much in the same condition as before the occurrence. All the symptoms of peritonitis above detailed lasted with but little amelioration for three days, except the temperature, which, on the fifth morning after the initiatory chill, was but 104⅘°.

"Between five and six days after perforation had occurred the symptoms of peritonitis began to subside, and after a protracted sickness and slow convalescence complete recovery finally resulted.

"*Treatment.*—It has been agreed by all clinicians that in peritonitis, from whatever cause it may be due, the one remedy, *par excellence*, is opium, and it was on this remedy principally that the writer from the onset relied. The drug was administered in large and increasing doses, frequently repeated : beginning the treatment with an equivalent of two and a half grains of opium every three hours, both the amount administered being quickly increased and the interval between doses proportionally diminished.

"The opium was used sometimes in the form of hypodermic injections of morphia, sometimes the deodorized

tincture of opium, and again, but not frequently, in the form of suppositories.

"Monsell's solution and acetate of lead were both employed to control the hemorrhage from the bowels, but there can be no doubt that much more advantage was obtained from the use of twenty minims of fluid extract of ergot hypodermically, which, indeed, was, after the second bloody stool, solely employed as a hæmostatic.

"In the hyperpyrexia, quiniæ sulph. in large doses (ten grains every two hours) frequently repeated was employed, and when the thermometer reached 106° its hypodermic use was also resorted to. The writer was tempted once or twice to resort to the immersion of the patient in a cold bath, but he has seen it so often employed and with so little real benefit and so much decided harm that he was deterred from its use. Sponging the body of the patient, however, every fifteen or twenty minutes thoroughly with vinegar and water was persistently employed. The writer has rarely seen the combined use of large doses of quinine and the sponging system, when judiciously used, fail to reduce even the greatest amount of hyperpyrexia.

"The amount of nourishment allowed the patient was reduced to the minimum consistent with safety, and after the second day of the peritonitis nutrient enemata were as much as practicable substituted for gastric alimentation until the peritoneal symptoms had subsided."

A CASE ILLUSTRATING THE FUTILITY OF TREATMENT IN TRAUMATIC TETANUS.

Most reported cases of tetanus are reported to illustrate successful treatment. The following from Dr. J. G. Stair, of Manteno, Ill., is therefore instructive as showing the other side: "A robust young man stepped on a nail, causing a penetrating wound of the right foot. Tetanic symptoms began one week later: trismus, opisthotonos, profuse sweatings, a temperature not rising above 101° F. at any time, the arms and lower limbs not affected until just before death, which occurred in three days. The medical treatment, which was decidedly heroic, consisted in thorough purgation with calomel at the start. This was followed by large doses of bromide of potassium. First dose two drachms and then one drachm every two hours. Alternated this with twenty minims fluid extract of gelsemium every two hours. This treatment controlled the paroxysms for a short time. Then in place of the gelsemium scruple doses of chloral were given, limiting the amount to eighty grains in twenty-four hours, with milk and beef-tea *ad libitum*. On November 27th, Dr. Scobey, of Kankakee, saw the case with me. He concurred in the diagnosis and treatment, and suggested administering atropine $\frac{1}{25}$ grain and morphine $\frac{1}{4}$ grain, hypodermically. This was carried out with only temporary relief. After this I administered chloroform and ether—equal parts—with some relief from the violent tonic spasm; but as soon as the effect of the anæsthetic had disappeared the paroxysms returned with increased severity. The night of November 27th, Dr. Rouleau, of Manteno, was called to see the case. He agreed with us in the diagnosis, and suggested grain doses of morphine hypodermically. We also decided to give infusion of tobacco by the rectum. These measures were employed with apparently no benefit except to quiet him for a short time. The potassium bromide, gelsemium, chloral, hypodermic injections of atropine and morphine, inhalation of chloroform and ether, and injection of tobacco infusion in rectum, were all administered in large doses, but not beyond the limits of safety.

"Dr. J. R. Beck has collected (*St. Louis Medical and Surgical Journal*, June, 1872) thirty-six cases of traumatic tetanus treated essentially by chloral in which a recovery took place in twenty-one instances. Dr. H. C. Wood has tabulated ('Treatise on Therapeutics,' pp. 292, 293) eighteen cases resulting in nine recoveries and nine deaths, which were treated mainly by chloral. Bartholow states ('Materia Medica,' etc., p. 448) that H. C. Wood tabulated fifteen cases which he has collected in which the bromide of potassium was the chief or only agent, and of these but two died.

"The question arises, would curare, physostigma, cannabis indica, thorough relaxation with lobelia, or complete intoxication with alcoholic liquors have been the means of saving the patient in this instance? I employed the most reputed and well-tried remedies as recommended by such high authorities as I have referred to."

Progress of Medical Science.

Chyliform Ascites.—Milky effusion into the abdominal cavity is of rare occurrence, especially in children. A well-marked case of this kind was observed recently by Dr. Letulle (*Revue de Médecine*, No. 9, 1884). The patient was a boy, aged eight years, who some two years before coming under observation had a first attack of articular rheumatism. A second seizure occurred about a year afterward. Both times the heart was implicated in the rheumatic affection. Œdema, ascites, and dyspnœa soon developed. Intense pains in the lumbar region came on. Anorexia, vomiting, insomnia, and restlessness were added to his sufferings. It was decided to remove some of the fluid from the boy's belly, and on puncture about two quarts of a milky liquid escaped. Microscopical examination showed it to be largely composed of emulsified fat. In commenting upon this and similar cases, the author concludes that, in all cases of chyliform ascites in which an autopsy was obtained, the chief lesion consisted in chronic peritonitis. This was due either to tuberculosis or cancer, or to simple serofibrinous inflammation. A chronic inflammatory element was almost constantly present, and must be held largely responsible for the occurrence of chylosis ascites. The same applies to chylous pleurisy. A granulo-fatty degeneration of the products of inflammation, namely, pus and fibrin, accounts for the milky appearance of the effusion. In the serum of the latter the oily globules and granules are suspended, forming a real emulsion.

Total Extirpation of the Uterus.—Dr. Muller, of Berne, performs total extirpation of the uterus in the following manner (*Deutsche Med. Zeitung*): During the operation the abdominal aorta is compressed, and the uterus turned out through an incision in the posterior wall of the vagina. After securing the broad ligaments and vaginal tissues with provisional ligatures, the uterus is then divided vertically with knife and scissors into a right and a left half, each of which is drawn down and the ligaments secured just as in the treatment of pedicle of uterine polypi, the uterine tissues divided about one centimetre from the ligature. The wound in Douglas' pouch is not closed, nor is drainage employed, the only dressings being dry carbolized gauze, and daily washing with corrosive sublimate. In the four cases in which the author employed this procedure the result was perfectly satisfactory, probably from the very slight loss of blood which this method entails.

Reflex Irritation as a Supposed Cause of Abortion.—Dr. Jamieson, of Melbourne (*The Australian Medical Journal*, October 15, 1884), believes that the influence of reflex irritation in the production of premature confinement is often much overrated. And, though we are getting to have more correct notions about the efficient causes of the spontaneous appearance of premature labor, there is still a good deal of difference of opinion. Among the older writers, what we now consider trifling matters often had great, and quite undue, importance attached to them. Smellie, one of whose marked characteristics was robust common-sense, went so far as to say, "Abortion may be likewise occasioned by uncommon longings for things which cannot be soon or

easily got, or such as the woman is ashamed to ask for, especially in her first child, namely, different kinds of food and drink. . . . These cravings, therefore, though they appear unreasonable and improper, must be satisfied, and the mother ought to shun everything that is disagreeable to the senses, because miscarriage may also proceed from surprise at sight of strange and horrible objects." Accidents of all kinds, operations of even the slightest severity, and peripheral irritations of the most various kinds and degrees, have all been supposed to have a strong tendency to favor the occurrence of abortion. Dr. Jamieson then relates the case of a young married woman, aged twenty, in the seventh month of pregnancy, who was admitted to the Alfred Hospital on May 31st suffering from severe burns. They were of the third degree, and extended over both buttocks and a large part of the backs of both thighs. There was also a patch below the umbilicus, about one inch and a half in diameter, and others on both legs below the knee. Large sloughs separated, and at one time recovery was doubtful. Nevertheless, pregnancy went to the full term, and she was delivered easily of a healthy, well-developed child, on August 9th. At that time there were still large unhealed surfaces on the thighs secreting pus copiously; and yet, though labour occurred, and the puerperal period was gone through, in what might be called an atmosphere of pus, she had no bad symptoms, and, in fact, made an excellent recovery. This case has, therefore, according to the author, a double interest, as showing, not only how completely without effect on the course of pregnancy may be an accident, attended both with intense peripheral irritation, and with severe shock to the nervous system; but also as illustrating very well the need of something more specific than ordinary pus, even in abundance, in the lying-in woman's surroundings, if febrile conditions are to be excited.

Hæmoglobinuria and Syphilis.—The pathogeny of intermittent or paroxysmal hæmoglobinuria is shrouded in obscurity. The notion that it is related to malarial disease is now almost abandoned, at any rate as a universal proposition. Its dependence upon exposure to cold led to the hypothesis that it was due to vascular engorgement of the kidney, and that in that organ the blood-cells were broken up and the hæmoglobin excreted. Such a theory may be called the vaso-motor hypothesis, but it cannot be invoked in many cases. Others have suggested that the corpuscular disintegration was due to the absorption of bile acids into the blood, or to some less manifest change in the fluid. That the syphilitic poison is sometimes a factor, as some allege, is supported in a few cases mainly by the effects of treatment. A case from Professor Rossbach's clinic is recorded where a child of nine years, the subject of inherited syphilis, became liable to the affection on the slightest exposure to cold or even slight changes in temperature. A resort to iodide of potassium, and to mercurial inunctions, was followed by a freedom from liability to the attacks which could but be regarded as a cure; for even immersion in ice-cold water of the extremities, and once of the whole body, failed to reproduce the hæmoglobinuria after this course of treatment.—*London Lancet.*

Aggravated Chorea cured by Conium.—Dr. Sinclair, in the *London Lancet*, November 29, 1884, reports a case of severe acute chorea, occurring in a boy aged twelve. On admission, and when first seen in bed, he was tossing about and did not seem to be able to lie still for a moment. His upper and lower limbs were in constant movement, especially the latter. The head was at times jerked to the one side and at times to the other, and occasionally backward. The whole body was from time to time bent backward like a bow. If asked to protrude the tongue he jerked it out, sometimes to the one side and sometimes to the other. The muscles of expression also participated in the movements, the eyebrows being raised from time to time, but on the whole the face was placid. There was an auriculo-systolic murmur at the apex. In summing up the history of this case, the author remarks that "on both the paternal and maternal side, but especially the former, there was a well-marked rheumatic tendency, although the patient himself never suffered from any rheumatic affection beyond the pains in the limbs complained of before the onset of the attack for which he was under his care. This case was without exception the most aggravated attack of acute chorea he ever saw. The poor boy's sufferings were most painful. Arsenic and bromide of potassium in full doses had been tried before he saw him, but without any effect. It will be observed from the clinical record that although he was so ill as to require the administration of chloroform on the day after admission he immediately improved after four one-drachm doses of conium juice, and he continued to improve steadily under its use. It was not found necessary to resort to the enormous doses recommended by some authors, and derided by others. Ten-minim doses of tincture of belladonna appeared to have no effect on the incontinence of urine, which rapidly ceased on the administration of fifteen-minim doses four times a day. The cardiac murmur also disappeared under treatment. There has been no return of the disease since the boy left the infirmary."

The Heredity of Longevity.—It would be interesting to study more closely, thinks the London *Lancet*, in the case of centenarians and other aged people, the ages of their near relatives and immediate ancestors. It will probably be found not rarely that long-lived persons have not been stronger than those who have been short-lived. They have their "often-infirmities" like other people. It will also frequently be found that their brothers and sisters have been as short-lived, or more so, than others. At the same time an element of heredity may not seldom be traced, or may have to be recognized, for we have not yet sufficient data for dogmatic conclusions. We are able to give to-day some few more particulars of the ages of the immediate family relatives of Sir Moses Montefiore, which we have reason to believe are correct, though in one particular at variance with a statement in a previous number. Thus one parent died at seventy-nine, one at eighty-three, his grandfather at eighty-seven, his grandmother at ninety-three, a brother at seventy-five, another at sixty-nine, a sister at eighty-four, another at seventy-nine, another at eighty-two. These nine ages at death give an average longevity of eighty-one years. The first four—those of the parents and grandparents of Sir Moses—give an average of eighty-five years.

The Relation of Certain Diseases of the Eye to Gout.—The Bowman Lecture for this year was delivered by Dr. Jonathan Hutchinson, who selected the above subject for discussion. The following is a brief summary of the author's views (*Lancet*, November 29, 1884): It has been shown to be probable that there are many different forms of inflammation of the eye, or of parts of it, which are in connection with gout. Some of these are very peculiar and specialized types of disease, and have already been accorded distinctive clinical names; others quite as distinct are not as yet so well known, and of others we may say that they are to be distinguished from other inflammations of the same structures not so much by their features as by their cause. Of all we may assert that they are infrequent; some, if we confine ourselves to well-marked types, are distinctly rare. We have divided these different affections into two groups: 1, those which go with acquired, humoral or renal gout, and 2, those which depend upon the inheritance of structures damaged, or at any rate specialized, by gout in predecessors. It is needless to repeat that in almost all cases of acquired gout there is inheritance also, and that in many in which the disease is chiefly caused by inheritance, some modification or increase may have been derived from personal habits. Still, the difference between the two classes of affections is very marked. In the one, attacks of a tran-

sitory nature are the rule, and these attacks are often acute and attended by much pain. In the second group, although a tendency to temporary recovery and recurrence is often observed, yet there is a great proneness to chronicity and persistence. The invasion is often insidious, but the disease is usually in the end destructive. In the former group we have placed hot eye, sclerotitis, recurrent iritis, and retinitis hæmorrhagica. All these are diseases of adult life. In the second group we have insidious disorganizing iritis, relapsing cyclitis, certain forms of soft cataract, and perhaps some of primary optic neuritis. Not only are there clearly marked clinical differences between the two classes of affections, but the difference in treatment is equally marked. In the first the well-known measures against gout must be taken—a restricted regimen, alkalies, colchicum, and aconite, and liberal counter-irritation. In the second we must use tonics, and although counter-irritants are here also often valuable, we cannot trust to any measure as really curative short of complete change of climate.

Nephrectomy for Calculous Pyelitis.—The dependence of the issue of nephrectomy upon the healthy state of functional activity of the remaining organ is again shown by Dr. E. Sonnenburg, who details a fatal case in which the non-extirpated kidney exhibited no definite structural change. The case was that of a woman, fifty-two years of age, who had suffered for months from pain in the right loin, accompanied by fever, wasting, and polyuria. She came under Dr. Sonnenburg's care in August, 1884, when the presence of a large fluctuating tumor in the right half of the abdomen was ascertained, and on aspiration pus was drawn off from it. Nephrectomy by the abdominal incision was performed on August 25th. The operation was difficult and tedious, the thin wall of the cyst rupturing in the removal. The whole pedicle was secured to the wound, but it was found impossible to suture the peritoneum. The organ was converted into a chambered, pus-containing sac, with numerous thin-walled outlying cysts, and a large branching calculus was lodged in the dilated pelvis. Hardly any renal tissue remained. Collapse followed, terminating in death on the second day, and during the whole interval no urine was secreted. There was no peritonitis; the left kidney weighed a little over six ounces and was anæmic, but histologically almost normal, except for some localized fatty degeneration of the renal cells and slight increase in places of the interstitial tissue. The fatal issue of the case could not, the author thinks, be attributed to the shock of the operation and the collapse alone. But the condition of anuria, the cause of which remains unexplained, was in the main answerable for this result.—*Berliner Klinische Wochenschrift*, November 29, 1884.

Hysterectomy for Uterine Cancer.—In a recent discussion of the treatment of carcinoma uteri by extirpation of the uterus, before the Paris Academy of Surgery (*Bull. Gén. de Thérapeutique*), most of the surgeons agreed with the opinion expressed by Verneuil and Polaillon, that hysterectomy would be a very good operation at the beginning of cancer, if it were less dangerous; but with the progress of surgery its dangers may be lessened. It is, therefore, an operation for the future. But under the present conditions, the mortality being one in three, the surgeon has not the right to resort to it, because fortunate results from it are far from being frequent.

A Case of Transformation of Scirrhus into Encephaloid Cancer.—Dr. Guermonprez, of Lille, has published in the *Gazette des Hôpitaux*, October 11, and November 4, 1884, some observations which confirm the view, that characteristic scirrhus may be at times transformed into true encephaloid. Velpeau pointed out the fact that all scirrhous cancers were not identical, and described an atrophic and a lardaceous form, the latter having a more rapid evolution. In the case cited, a traumatism received two years before death, is supposed to have determined the metamorphosis of the growth. The scirrhus which began in the mammary gland invaded the bony and cartilaginous structure of the fourth rib, and from this point to the tracheo-bronchial ganglionic mass, there was a bridge of new growth following the lymphatic vessels and resembling Gruyère cheese both in consistence and color. The encephaloid character was marked in the principal glands of the tracheo-bronchial group; also in the lower part of the sterno-mastoid, in the axillary and supra-clavicular glands of the same side. A group of the bronchial glands pressing upon the pneumogastric, where it crosses the bronchus, resulted in dyspnœa, cyanosis, and finally death, before the disease had produced a marked degree of cachexia.

Spermatorrhœa and Psychical Impotence.—From an exhaustive study of the subject, Dr. Armangué, of Barcelona, arrives at the following conclusions: 1. Spermatorrhœa and impotence may have as a cause, a distinct derangement of the intellect. 2. In such a case, treatment should be directed especially to the mind. 3. All remedies will be futile unless you succeed in convincing the patient that their administration will be followed by a cure. 4. In the moral treatment, the intelligence, education, and preoccupation of the patient, as well as the idea he has formed concerning his disease, must all be taken into account. 5. These affections are very common, quite distressing, and frequently of long duration. 6. The condition is often aggravated, and may even be produced by reading works on diseases of the genital organs. 7. You may often cure the patient by placing in his hands carefully chosen modern works on the same subject.—*Journal de Médecine*, November 1, 1884.

The Diagnostic Value of Tubercle Bacilli in the Urine.—So difficult is the positive diagnosis of tubercular disease of the kidney and urinary tract, that, where tuberculosis of the lung does not co-exist, it has frequently been regarded as impossible. A further contribution to our knowledge of the subject recently appeared in the *Pester Médico-chirurgicale Presse*, No. 39, 1884. Dr. Arthur Irsai claims that the presence of Koch's bacillus in the urine establishes beyond question the diagnosis of urino-genital-tuberculosis. He gives two cases in illustration of his views, in both of which the bacillus was found in the urine by the method of Ehrlich. The autopsies showed tubercular deposits in some portion of the urinary system. In one case there was also phthisis and bacilli were found in the sputum a month before death. Here the symptoms had pointed to a cysto-pyelitis, but the excessive loss of flesh and strength caused suspicion of a severe disease of the urinary organs. This was confirmed by the discovery of the bacillus in the urine.

White of Egg in Obstinate Diarrhœa.—Celli has recently called attention to the curative properties of the albumen of hen's eggs in severe diarrhœal affections. In a discussion before a medical society in Rome, he advocated its use, and related two cases of chronic enteritis and diarrhœa, which, having resisted all therapy, speedily made complete recoveries under the use of albumen. The same diet is strongly recommended in the diarrhœa accompanying febrile cachexia, and in that of phthisis. In two cases of diarrhœa dependent upon tertiary syphilis, it was found of no avail. On post-mortem examination diffuse amyloid degeneration of the arterioles of the villi was found in these cases. The mode of administration is as follows: The whites of eight or ten eggs are beaten up and made into an emulsion with a pint of water. This is to be taken in divided quantities during the day. More may be given if desired. The insipid taste can be improved with lemon, anise, or sugar. In case of colic a few drops of tincture of opium may be added.—*Allgemeine Medicinische Central Zeitung*, October 8, 1884.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 10, 1885.

SANITARY IMPORTANCE OF EPIDEMICS.

THE knowledge of the fact that cholera prevails most severely among the filthy classes of a city makes this scourge a most important factor in securing sanitary cleansing of cities which it threatens. Already has its presence in Europe excited a very salutary agitation in this community, the effect of which is seen in increased activity of the Board of Health, the organization of Sanitary Reform Associations, and a large newspaper discussion of old nuisances against the public health. The current topics which now attract public attention are the streets, the manure-heaps, the slaughter-houses and filthy trades, and the tenement-houses. It is interesting to note the progress of discussion of these sources of ill-health. Until recently we have been assured that the streets were in a state of sanitary cleanliness; now it is discovered that they are very filthy. On the strength of that announcement the shrewd Commissioner puts $25,000 more in his already plethoric estimate. The wise men of the Board of Estimate grant that sum, but allow it to be used only in case of the actual prevalence of the epidemic. So the streets are to remain as in the past, unless we are blessed with an outbreak of cholera, when they are, for the first time, to be well and thoroughly cleaned. The manure question suddenly assumes great importance. For years the people living on the east side of the city have complained to the Board of Health of the suffocating stenches which arise from the enormous collection of manure at the foot of Forty-sixth Street and East River, and envelop a large section of the best part of the city, but their complaints have been unavailing. Under the pressure of public sentiment, the Board of Health annually assaults this gigantic nuisance with paper pellets, but there it has stood, and still stands, unmoved, towering on the river front like a very Gibraltar. But with the rumor of an approaching epidemic, the long-suffering citizens have determined to abate this nuisance against which the health authorities have proved so powerless, and a committee of energetic ladies have gone at once to the Grand Jury and demanded its assistance in bringing this old offender against health and decency to justice.

The result of this flank attack is, that the manure-heap must go. Here let us express the hope, that this organization of women, for sanitary reform, will not disband, but rather enlarge the scope of its work. There are innumerable sources of ill-health in this city which such a society can reform. Again the question begins to be asked, what will be the effect upon the public health of fifty to seventy-five slaughter-houses and offensive trades connected with them, scattered over large areas, if cholera appear? If this inquiry lead to the practical conclusion that all the slaughtering for this city can be done inoffensively in two abattoirs, one upon either river front, the reform would not be dearly purchased by a cholera outbreak. Such a salutary change in the methods of supplying the city with meat, must be largely the result of popular agitation, for a health board rarely has the courage to persistently struggle with such forces as the slaughtering interests command. At one time the Board did adopt an ordinance which would have rid the city forever of this fruitful sources of nuisances, dangerous to life and detrimental to health, but it had not the firmness to enforce it, and finally rescinded its action. Another fruitful topic of discussion in times like these, is the tenement-house. No subject so interests a certain class of reformers as the condition of the poor in tenement buildings. There is a stereotyped style of setting forth the miseries of the poor in these abodes of wretchedness which appeals with great force to the public conscience. The real value of this agitation is the renewed efforts of the Board of Health to improve the homes of the poor. Inspections are more frequent and thorough, and radical defects are remedied. It will be safe to estimate that every cholera agitation effects reforms in tenements, which diminish permanently the sickness and death-rate of the poor fully five per cent.

It thus becomes apparent that great epidemics are by no means unmitigated evils. They teach and enforce lessons as no other master can. It is in vain that we urge sanitary reforms and improvements when there is no existing or threatening epidemic. Filthy streets, unsanitary tenements, garbage-heaps, manure-dumps, and unhealthy trades abound, in spite of protests of citizens. Boards of health, even, become indifferent, and legislative bodies diminish or altogether discontinue appropriations for their work or existence. But when an epidemic, like cholera, looms in the horizon, and tidings of its devastation of communities who are noted for their filthy habits reach us, all is changed. Citizens anxiously inquire, What shall we do to prepare for its reception; health officers assume great apparent activity; the grand jury inquires into the efficiency of the Board of Health; and the Board of Estimate lavish the public money with unstinted hand. For the time the city is placed in good sanitary condition, the general sickness rate rapidly falls, and the mortality is proportionately diminished. The result of this sanitary cleansing proves that if we could always live in the immediate apprehension of an epidemic, New York would be the healthiest city of the world.

ON THE CURABILITY OF PHTHISIS.

IN the early part of the present century phthisis pulmonalis was regarded as almost uniformly fatal. "No fact," says Andrae, "demonstrates that phthisis has ever been cured, for it is not art which operates in the cicatrization of cavities." Louis admits that a cure may rarely take place, but the disease must then be limited, and "the result is fortuitous." In the last thirty years

or more, however, since Professor Hughes Bennett began to advocate the sthenic treatment of the disease, the views as to its course and termination have greatly changed. Now we are told by the last-named author that phthisis is "not considered to be uniformly or even generally fatal," and that treatment can, in the great majority of cases, prolong life, while in many "a complete and permanent cure may be effected." The inference is also drawn from post-mortem examinations that one-fourth to one-half of persons who die after the age of forty have had an apical phthisis which was cured. Dr. Richard Quain and Dr. Jas. Henry Bennett have expressed similar hopeful views.

On this side of the Atlantic, among the optimists, Dr. James R. Leaming states his belief that nine-tenths of all forms of phthisis commence with interpleural exudation, "which is removable, when fresh, by proper management;" from which the inference is to be drawn that nine out of ten of cases of incipient phthisis can be cured. Professor A. L. Loomis states that chronic pulmonary phthisis is not necessarily a fatal disease; its morbid processes may be arrested in a large proportion of cases. Recovery has taken place in one-sixth of Dr. Loomis' recorded cases in the past ten years. The views of other modern authors have a like hopeful character.

Dr. Roberts, whose opinions coincide with those of Dr. James Pollock, in his "Practice of Medicine," states that there is now ample evidence to prove that phthisis may, in certain cases, be completely arrested or cured; while in a large proportion its progress may be greatly delayed by appropriate treatment, and life rendered fairly comfortable.

Niemeyer states that death is the most frequent result of all forms of pulmonary consumption, and is the sole termination of tuberculosis, but that in the forms of the malady which are dependent upon pneumonia, an improvement and approximative recovery are not as rare an occurrence as is usually supposed.

A. Flint states that the prognosis in cases of pulmonary tuberculosis is extremely unfavorable . . . yet the mortality has undoubtedly diminished within the past ten or fifteen years. The same observer has collected a very small number of cases in which the disease ended in recovery spontaneously, *i.e.*, without any hygienic or therapeutic measures having been employed.

Sir Thomas Watson, following Dr. Latham, suggested a similar view, viz., that in certain forms of "unmixed" phthisis a natural cure by the contraction and cicatrization of a vomica may by a possibility take place. He places the average duration of a case of phthisis at two years. Older authorities, such as Louis, Bayle, and Gregory, estimated the ordinary duration at from six to nine months, while Dr. C. J. Williams found the average of 198 cases to be over seven years.

Dr. Wood, in his "Practice of Medicine," announces his belief that phthisis is occasionally cured; and he further believes that each tubercle has a tendency toward health, and if alone would in time end in perfect recovery; so that the great fatality of phthisis is due to the continued predisposition which causes the repeated deposition of new tubercles.

The statistics of the Registrar-General of England how that phthisis does not cause so many deaths proportionally as it did in former years. The reports of the Massachusetts State Board of Health also indicate that up to within a few years there has been a steady decline in the comparative death-rate of phthisis since 1857.

The question may be fairly raised now, however, whether there has not developed a too hopeful view as to the prognosis of phthisis in the minds of the medical profession. It is true, as is stated by Dr. Beverley Robinson in a suggestive paper recently read before the Practitioners' Society, that when a patient is in a position to command all the diagnostic skill and therapeutical resources of the medical profession, much may be done for him. But when we come to the vast mass of humanity which has to earn its living by continual toil, the problem is a different one. Is there a hospital or dispensary in the whole country which can report cases of phthisis cured? If so, their fortune is an unusual one. Perhaps every practitioner has treated or heard of one or two cases of phthisis in which the disease has ceased its course and the patient regained perfect health. But against these are the death-rates showing that from twelve to fifteen per cent. of mortality is from consumption.

It should be borne in mind that the gentlemen who write our text-books and express optimistic views regarding phthisis, are generally physicians in the best practice, who see many patients that are able to go South or go West; patients who are intelligent enough to understand and willing to utilize strictly and carefully every possible measure which will tend to restore them to health. The country doctor who treats the farmer's wife or the small tradesman, and the city doctor who treats the mechanic, the clerk, the domestic, and the laboring man, may have a different story to tell. It is certain that we can control the disease and prolong life more successfully than formerly. But as to absolute cures, perhaps Louis saw as many as we do to-day.

SOME NEW FACTS AND A NEW THEORY AS TO THE ASSIMILATION OF IRON.

In Hoppe-Seyler's *Zeitschrift für Physiologische Chemie*, ix. B. 1 Heft., Professor G. Bunge has contributed a thoroughly original article upon the subject of the assimilation of iron; and he presents some new facts which may prove to have an important practical bearing. For in these days of sthenic therapeutics, few drugs are more frequently and perhaps indiscriminately administered.

The first question propounded by Bunge was: in what form is iron normally absorbed and assimilated? Out of what compound is hæmoglobin built? Necessarily in such a substance as the yolk of eggs, iron exists in the form in which the blood takes it up and uses it, since we have hæmoglobin before there is any digestive apparatus. By careful analysis there was obtained from two hundred yolks, thirty-four grammes, or about one ounce, of a natural iron compound. This compound was split out from a more complex proteid by a certain ferment action. Bunge showed by several tests that the new compound was not an iron salt or an iron albuminate. It was very complex in composition, containing even more atoms than hæmoglobin. Believing that hæmoglobin is formed by a splitting up of this body after it is absorbed into the blood, Bunge gives it the name of

hæmaglobinogen or hæmatogen. Analyses showed it to be composed as follows :—

$$C_{42\cdot11}\ H_{6\cdot08}\ N_{14\cdot73}\ S_{0\cdot85}\ P_{6\cdot19}\ Fe_{0\cdot29}\ O_{21\cdot95}$$

Compared with hæmoglobin it has less C, H, and N, but it has one-third more oxygen and ferrum, and about seven times as much phosphorus.

Believing, then, that out of the protoplasm is split up by a ferment hæmatoglobin, and out of this, hæmoglobin, Bunge contends that our natural foods contain no inorganic iron compounds, that *inorganic iron salts are never absorbed and assimilated*, and that iron takes part in our nourishment only in the form of complicated organic compounds which are the result of the life-processes of plants. The vegetable world caters to us for our iron as well as for the other elements.

Naturally the question at once arises, How is it that inorganic iron salts do undoubtedly relieve anæmia and assist hæmatosis. The answer is that these salts in some way prevent the organic iron compounds from being decomposed and made unassimilable. There is always enough iron in a natural diet for the wants of the system, but this natural supply may be injured by abnormal fermentations in the stomach or intestines. Hæmatoglobin is very easily decomposed, especially by the alkaline sulphates, which are liable to appear when there are butyric and other fermentations. Hence, in prolonged gastro-intestinal disturbances sufficient of the natural iron compound fails to reach the blood. The anæmia resulting can be corrected by protecting the hæmatoglobin with large doses of iron or by treating the gastro-intestinal troubles directly. The hydrochloric acid of the stomach is a natural antiseptic and protector of the food iron. In chlorosis, Zander has shown (*Virchow's Archives*, Bd. 84, 1881), that large doses of this acid will produce more favorable results than iron itself. The high estimate placed upon the muriated tincture of iron may be explained upon some such theory as Bunge has offered.

The practical inference to be drawn is that the ordinary albuminates, malates, lactates, etc., of iron are no better, no more likely to be assimilated than the inorganic salts. The former may be given for special reasons, but the muriated tincture is after all the best form to use, when the stomach will allow.

IS PNEUMONIA AN INFECTIOUS DISEASE?

Within a comparatively short time the literature on the infectious nature of pneumonia has grown to considerable dimensions. Most of these recent communications are of French or German origin. In England, but quite especially in our own country, original contributions to the subject continue to appear rather tardily, and, as it were, with considerable hesitancy of conviction. There can be no doubt, however, that the current drift of the most competent opinion in the profession is toward an acceptance of the specific and infectious nature of the malady. The October number of the *Revue des Sciences Médicales*, contains a good *résumé* of the entire subject in its various aspects, theoretical, clinical, and experimental. It must be confessed at the outset, that some confusion has been created by the mingling of cases well-observed and equally well-recorded, with those of a decidedly contrary kind. One point is quite incontestable, namely, the fact that lobar pneumonia may assume the proportions of a quickly-spreading epidemic.

Moreover, such epidemics are by no means of quite infrequent occurrence. Now, it is impossible to explain them through the sole agency of meteorological influences. Nor is "taking cold" an adequate explanation of the origin of single cases of pneumonia. If, therefore, we can dismiss cold, if we accord to hygienic conditions, acclimatization, and general surroundings only their proper share in the etiology of the disease, which is the production of predisposition, then we must seek for other causative agents. Something outside of the body must, after entering the organism, be capable of suddenly setting up a typical disease, with a well-marked natural history. The assumption of a specific microbe is a very natural one, and the discovery of the same and its repeated observation by competent physicians are already matters of record. When the question is put, Is pneumonia directly transmissible from man to man? clinical experience answers that the contagion of the disease must be a feeble one. In this respect the pneumonia microbe would seem to resemble the supposed germ of malaria in manifesting the properties of a telluric poison.

This part of the question is still quite obscure, which is due in no small measure, perhaps, to insufficient knowledge concerning the micrococcus of pneumonia. Friedländer, Talamon, and Fränkel each claim that their particular bacterium is the true pneumonia producer.

But it is well to remember in all such contentions, that it has yet to be shown that pneumonia may not arise from various kinds of microbes. This brings us to the question of the unity of the disease. And here again we are met by strongly opposing views. Thus, at the recent German Medical Congress, Jürgensen and Fränkel upheld it, Friedländer doubted it, while Rühle, Bäumler, and Rosenstein emphatically denied it. Secondary inflammation of the lungs should certainly be distinguished from the primary variety. For the acute lobar pneumonia of asthenic type can hardly be considered to be identical with those asthenic forms that so frequently complicate typhoid fever, chronic nephritis, or cerebral disease.

Again, the unicist view is not upheld by the clinical history of the disease as well as it might be. The physical signs may be the same in all cases of pneumonia. Yet that merely shows that there is fibrinous inflammation in the lungs. Now, it seems that the pulmonary parenchyma responds to irritation in a certain way, just as mucous tissue does. But we should not, therefore, conclude that there is only one cause which sets up this reaction.

Pathological identity of lesion should not be used as an argument in favor of identity as regards etiology. There are pneumonias and pneumonias, just as there are different kinds of catarrh. For the present, therefore, it seems best to distinguish two principal varieties of pneumonia, and to call one simple, the other, specific pneumonia.

THE MAYOR'S MESSAGE AND THE BOARD OF HEALTH.

The message of Mayor Grace was sent to the Board of Aldermen on the 5th inst. It contains some suggestions in reference to matters of public health which are both

timely and creditable. Appreciating the fact that any moneys spent in rendering our city more healthful and decreasing the death-rate is a real economy, he urges the strengthening of the Health Department, as well as increased appropriations, that would afford it the necessary means of placing the city in the best possible sanitary condition. Undoubtedly there is much to be done in this direction, and much money will be required, especially in the matter of purifying our shamefully crowded districts. Public opinion will certainly uphold Mayor Grace in the stand he has taken, and the community will bear willingly their part of the burden. The business men, more than any other class, know only too well the loss that would fall upon their interests should the cholera come upon us, and find a filthy city ready to welcome it. Public health is even more necessary to public wealth and happiness than is the health of the individual.

Let the Mayor's suggestions then be heeded, and may the Health Board so co-operate with the Street Cleaning and Police Departments that the coming spring shall find us, enjoying as we do great natural advantages, a city the cleanest, healthiest, and safest in the country. The feeling of safety from pestilence would alone be worth thousands of dollars. For nothing is more certain than that anxiety and apprehension are potent predisposing causes toward the acquisition of disease liable to assume the dimensions of a wide-spread epidemic.

THE SUCCESSFUL REMOVAL OF A TUMOR FROM THE BRAIN.

Another triumph has been added to medicine and another tribute made to the practical value of physiological and experimental science. For the first time in history a tumor of the brain, having been precisely located by the symptoms produced, has been successfully removed by a surgical operation.

The patient was an inmate of the Hospital for Epilepsy and Paralysis at Regent's Park, and was under the care of Dr. Hughes Bennett and Mr. R. J. Godlee. He was a farmer, aged twenty-five, who had been in good health until three years before. He then began to suffer from paroxysms of twitchings in the left side of the face and tongue. Attacks of general convulsions with loss of consciousness supervened, and for two and a half years he continued to suffer from the local spasms and epilepsy. Then spasmodic twitchings of the left arm appeared, and the general convulsions ceased. After several months the arm became paretic and the left leg began to twitch. The patient suffered from violent headaches, attacks of vomiting, and had a double optic neuritis.

The conclusions drawn by Dr. Bennett were: first, that there was a tumor in the brain; second, that this growth involved the cortical substance; third, that it was probably of limited size, as it had destroyed the centres presiding over the hand, and only caused irritation without paralysis of the centres of the leg, face, and eyelids which surround it; and fourth, that it was situated in the neighborhood of the upper third of the fissure of Rolando.

It was decided to attempt its removal. Accordingly, on November 25th, Mr. Godlee trephined the skull, and removed a triangular piece of bone over the region corresponding with the upper part of the fissure of Rolando. After the bone was removed, the dura mater slit up, and the cortex of the brain exposed, no tumor was visible. The ascending frontal convolution, however, seemed to be somewhat distended. An incision about an inch long was therefore made into the gray matter in the direction of the blood-vessels, and one-fourth of an inch below the surface a morbid growth was found. This was carefully removed, and proved to be a hard glioma about the size of a walnut. The superficial part of this was distinct from the brain-matter and was easily enucleated. The hemorrhage was arrested by means of the galvano-cautery and the wound brought together by sutures.

Since the operation the condition of the patient has been satisfactory. The temperature did not rise above 100° F. The mind has been clear, the lancinating pains, vomiting, and convulsions have ceased. A hernia cerebri has formed, however, and the paresis of the left leg has increased. The outcome of the case will be watched with the greatest interest, as opening up a new field for the display of diagnostic acumen and surgical skill. We say this while fully aware that the case in question is really alike in some respects to others that have been operated upon for traumatic epilepsy.

THE ACCUSERS AND THE ACCUSED.

The two communications bearing upon the ridiculous charges against the distinguished President of the Academy of Medicine are presented in this issue in response to a widespread demand for the detailed facts in the case. They can safely be allowed to speak for themselves, explaining an endorsement of the very just verdict of the Academy in unanimously vindicating the accused.

This action is final, and from the decision of the tribunal there is no appeal. The profession, with perhaps the exception of the accusers, has but one opinion concerning the outcome of this miserable business, and is more ready than ever to offset the value of a good name, an upright of character, and a well-earned scientific reputation, against the spirit which so plainly manifested itself, in making the charges and in zealously pressing them to their issue. Few medical scandals can afford a better lesson than does this one to such as seek by like means to elevate the character of the medical profession.

Disappearance of a Physician.—Some time ago Dr. Richard C. Brandeis, of this city, suddenly and mysteriously disappeared. He has not been seen since, and it is feared that he has committed suicide while insane. Dr. Brandeis enjoyed a high reputation as a laryngologist, and had acquired an excellent practice. We learn, however, that he was subject to severe attacks of neuralgia and of mental depression.

An Important Literary Event.—With the present year is begun the publication of the first encyclopædic work on medicine which the American medical profession has ever produced. Wood's "Hand-book of the Medical Sciences" is to be a comprehensive and complete presentation of the present status of medical science by American physicians.

News of the Week.

Demonstration of Koch's Cholera-Bacilli.—Dr. E. C. Wendt writes that he has received from Dr. Koch, of Berlin, a specimen of his cholera-bacilli. In order to give those physicians who may care to examine the specimen, an opportunity to do so, he has arranged to show it at the New York Post-Graduate Medical School, 224 East Twentieth street, on Wednesday, January 14th, and Friday, January 16th, from 5 to 6 P.M. The specimen was prepared by Koch himself from a pure culture, and shows well the the characteristic curved shape of the so-called comma-bacillus.

Unequal Justice.—Mr. G. W. Sparke states that Dr. G. T. Gadsby, of Mansfield, England, died on February 3, 1882, of diphtheria, contracted in precisely the same manner as that of Dr. Rabbeth. No notice was taken of the fact beyond a brief mention of the mode of death in the obituary notice. We are quite sure that other doctors have contracted diphtheria in this way, but have either recovered or died unnoticed.

New York State Medical Society.—The following are the titles of papers so far received, which will be offered at the Seventy-ninth Annual Meeting of the New York State Medical Society, February 3, 1885: Pelvic Abscess, Dr. W. W. Potter, Buffalo; Jequirity as a Remedy for Granulated Lids with Pannus, Dr. David Webster, New York City; Some Diseases of the Ear, Dr. D. B. St. John Roosa, New York City; Some of the Tests for Unilateral Deafness, Dr. O. D. Pomeroy, New York City; An Analysis and Refutation of the Theory of the Germinal Origin and Propagation of Disease, Dr. J. B. Graves, Corning; Meningitis as a Sequel of Pott's Disease, Dr. G. G. Monroe, Crary's Mills; Sane or Insane, Dr. E. H. Parker, Poughkeepsie; Uses and Limitations of Hydrochlorate of Cocaine, Dr. C. R. Agnew, New York City; Catalepsy in Very Young Children (8 m.), Digitalis, its many Indications (12 m.), Typhoid Fever in Infancy and Childhood (25 m.), Dr. A. Jacobi, New York City; Trichina and Trichiniasis, Dr. Harvey Jewett, Canandaigua; Treatment of Pelvic Abscess, Dr. Paul F. Mundé; Culture Experiments of Bacteria, Dr. William Hales, Albany; Senile Hypertrophy of the Prostate, Dr. A. C. Post, New York City; The Elements of Perturbation in Uterine Therapeutics, Dr. Frank P. Foster, New York City; Some Observations on the Use of Hydrochlorate of Cocaine, Dr. Thomas R. Pooley, New York City; Arteritis or Phlebitis the Sequelæ of Enteric Fever, Dr. Robert K. Tuthill, Poughkeepsie; Some Practical Points on the Treatment of Granular Lids, Dr. W. F. Mittendorf, New York City. A number of other papers are promised.

Sanitary Bureau Statistics.—During the year ending December 31, 1884, there were 30,527 births, 11,805 marriages, and 35,044 deaths. In 1883 there were 28,972 births, 11,566 marriages, and 33,982 deaths. Of the births 15,498 were those of boys. There were 292 twins. Of women over forty-five years of age 102 became mothers, and one woman over fifty years of age gave birth to a child. Of men over fifty years of age, 550 were fathers. Of the mothers, 429 had their tenth child, 200 their eleventh, 117 their twelfth, 76 their thirteenth, 32 their fourteenth, 15 their fifteenth, 8 their sixteenth, 1 her seventeenth, 2 their eighteenth, 1 her nineteenth, 2 their twentieth, and 1 her twenty-first.

The mortuary record shows for 1884, 9,194 deaths from zymotic diseases, 7,955 from constitutional diseases, 14,278 from local diseases, 2,267 from developmental diseases, and 1,350 from violence. During the entire year there was not a single death from small-pox. Fifty-four persons who died were more than seventy years of age.

Two hundred and twenty-six persons killed themselves, of whom 39 were women. The ages were—fifteen to twenty, 5; twenty to thirty, 52; thirty to forty, 60; forty to fifty, 41; fifty to sixty, 36; sixty to seventy, 20; seventy to eighty, 9; more than eighty years of age, 3. Fifty-four homicides were committed. One hundred and twenty-one persons, of whom 98 were women, lived beyond threescore years and ten. There were thirteen centenarians whose deaths were recorded.

Human vs. Bovine Vaccine Lymph.—The German Commission appointed to inquire into the subject of vaccination has, with the exception of the three members opposed to vaccination, unanimously declared for vaccination with humanized lymph rather than with that from the calf.

A New Disease, Gastritis Favosa.—Professor Kundrat, of Vienna, has recently reported a case of universal favus, in which the fungus finally reached the stomach and intestines and developed there. This is the first recorded instance in which the mucorineæ have been the cause of death, as it is the first of favus of the stomach and intestines. Indeed, the naked-eye appearance of the tumors in the stomach closely resembled the favus cups on the skin, and the fact that but little of the fungus was found in the intestine was explained by Professor Kaposi by their having undergone decomposition.

Attempted Suicide of Dr. Rudolf Tauszky.—Medical circles have been somewhat excited recently over the attempted suicide of Dr. Rudolf Tauszky. Early on the morning of January 4th Dr. Tauszky, who had been sitting up in his office, called to his wife to come into the room. She found him sitting in the dark, and after a few words a pistol was fired. Mrs. Tauszky ran out, and after help was secured the doctor was found lying unconscious on the floor, a bullet wound in his forehead and a five-chambered revolver on the floor near him. He was taken to the hospital, where it was found that his injuries were not severe, and he is now, we learn, convalescent.

Typhus Fever in the City.—A nest of typhus fever has been discovered in a West Side slum. Thirteen cases have been diagnosticated at date of writing. There have been isolated cases of typhus fever during the fall, but no outbreak since last winter.

Measures for Preventing Cholera.—The Board of Estimate and Apportionment has not seen fit to enable the Health Department, by an increased appropriation, to prepare for prospective cholera by thoroughly cleaning the town. The Health Department can have $50,000 in addition to the ordinary appropriation, but it cannot have it until the cholera shall have appeared here. The Street Cleaning Commissioner asks for an additional appropriation of $25,000 a month from April to October,

to be expended in keeping the streets absolutely clean in the tenement districts and plague-spots. Concerning this subject Mayor Grace says, in his message : "The hands of the Health Department should be strengthened in every way. While its expenditure, if the cholera should visit this city, will necessarily be increased in order that no preventive measure may be left incomplete, there should nevertheless be no wasteful, extravagant, or ill-considered use of the public moneys simply because the people are willing to spend liberally in order to avert a dreaded pestilence."

Sanitary Supervision of the Public Schools.—Concerning this subject Mayor Grace, in his message, recommends that the Board of Education institute a systematic and thorough examination into the sanitary condition of all school buildings.

The Cholera Bacilli Question.—Professors Ant. Ceci and E. Klebs, who have been studying the cholera question at Genoa, give a preliminary communication in *La Revista Internazionale di Medicina e Chirurgia.* They state that comma bacilli are not invariably present in the fæces of cholera patients, or in the intestinal contents of the cadavers of those who have rapidly succumbed to the disease. They also failed to discover the comma bacillus in the air expired by patients in the algide stage of cholera. In perfectly fresh cases, in which epithelium still existed *in situ*, no comma bacilli were found in the glands of Lieberkühn, although lymphatic cells abounded in the mucous membrane. So far as concerns their morphological characters, the comma bacilli and spirilli of Asiatic cholera proved identical with the comma bacilli and spirilli obtained by Finkler and Prior of Bonn, from the culture of the fæces of cholera nostras patients. The same forms of spirilli were found by Klebs in the diarrhœa of an individual suffering from pneumonia. In a later communication of Professor Klebs to the *Correspondenzblatt für Schweizer Aerzte* of December 7th and 15th, views more in harmony with those of Koch are expressed. The writer states that in the dejections of cholera nostras, bacilli similar to true cholera bacilli are seen, but that close study reveals some differences. Cultures must always be necessary for a positive diagnosis.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World :

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

Reviews and Notices.

A Manual of Diseases of the Throat and Nose, including the Pharynx, Larynx, Trachea, Œsophagus, Nose, and Naso-Pharynx. By Morell Mackenzie, M.D. Vol. II., Diseases of the Œsophagus, Nose, and Naso-Pharynx. Pp. 400. New York: William Wood & Co. 1884.

Diseases of the Throat and Nose, including the Pharynx, Larynx, Trachea, Œsophagus, Nose, and Naso-Pharynx. By Morell Mackenzie, M.D. Vol. II., Diseases of the Œsophagus, Nose, and Naso-Pharynx. Illustrated, pp. 550. Philadelphia: P. Blakiston, Son & Co. 1884.

This volume completes the work of Dr. Mackenzie, the first volume having appeared in this county from the press of the same publishers four years ago. The present issue constitutes the August number of Wood's Library of Standard Medical Authors for 1880.

The Record's notice of the first volume, in its issue of November 13, 1880, applies to the second volume, just published in this country, as regards the author's style and manner of dealing with the subject in general, and we can but repeat here the opinion then also advanced, that the work as a whole is a valuable contribution to the literature of medicine, and especially of the department of which it treats.

The author informs us in the preface of the second volume that he has been for twelve years engaged in the preparation of the work, a statement that no one can for a moment doubt who takes the trouble to examine the work itself, the painstaking details of which may with advantage be studied by those who nowadays write books by contract in the space of a few months' time.

We learn from the table of contents that two hundred and thirty-four pages of this volume are devoted to the consideration of the anatomy, examination, and treatment of the diseases of the gullet; two hundred and thirty-eight pages to the nose; fifty-two pages to the naso-pharynx; and ten pages to an appendix of special formulæ for topical remedies. The œsophagus usually being considered somewhat superficially by writers on the throat, we may regard the very considerable space given up to its consideration here as commendable.

The practitioner will be somewhat abashed when he turns to the subject of the diseases of the nose and finds that the author's armamentarium for rhinoscopy and treatment includes fifty instruments, of which wood-cuts are given, and as many more to which allusion is made in the text; but it will be found that many of these are not actually required, the author having a good-natured way of mentioning the contributions of his colleagues, whether of service or not. In respect to the somewhat thaumaturgical employment of spray producers in this country, the author says, "owing to the prevalence of catarrh of the naso-pharynx in America, and the necessity of thoroughly cleansing that cavity when diseased, great attention has been given by physicians in the United States to the subject of spray-producers, and both the air-pump and water-power have been brought into requisition to give force and steadiness to spray." The author might have truthfully added that steam-power had also been employed for this purpose. We feel like protesting against this implication respecting the greater prevalence of catarrhal affections in this country, since we are not aware that such a state of things has been shown to exist.

In regard to the treatment of acute nasal catarrh, not much has been added to our knowledge by the observations of the author. For the early stage of the disease he recommends five or seven drops of laudanum, which would seem to be a very inadequate treatment for the beginning of a severe cold in the head. Unfortunately our clients seldom consult us for colds in the early stage, and our experience in treatment is confined, for the most part, to permanently seated disorder.

In looking over the chapter on hay fever we must confess to experiencing disappointment; not but that the chapter is exceedingly full and complete, but that in respect to the causes of the trouble we are but little better informed than before. In respect to the etiology of hay fever the author says that the predisposing cause depends on a peculiar idiosyncrasy; had he paused just here it would have been well, but when he adopts the theory first advanced by Elliotson, in 1839, that the exciting cause is the inhalation of some pollen, we are, while not disposed in the least to cavil about the matter, quite convinced that it has been found more convenient to follow in this easy and well-trodden path, which has been so generally accepted without sufficient and conclusive evidence, than to pursue research in other directions. The author in reference to the treatment of hypertrophied mucous membrane of chronic nasal catarrh, of which much has been said of late, recommends the daily use of gum-elastic bougies, before attempting a surgical operation with cautery or écraseur, and somewhat facetiously remarks: "For though the introduction of the elastic cautery and the wire écraseur permits some relaxation of the rule under which surgeons were taught 'to cut through everything soft, to saw through everything hard, and to tie everything that bleeds,' the spirit of this simple instruction has, I fear, in recent years, sometimes influenced the young practitioner, and the nasal passages have occasionally been 'cleared' with a zeal and energy worthy of the industrious backwoodsman." And further, "I would also warn some of my younger *confrères* that as the appearance of the interior of the nose varies immensely in healthy persons, it is unnecessary, where no inconvenience is felt, to restore geometrical symmetry to the turbinated bodies, or to invest the lining membrane of the nose with artistic merit." We could add that in view of the energetic, and, perhaps, sometimes maladroit and inconsiderate, demolition of the interior structures of this useful organ the advice given seems not untimely. Mackenzie, moreover, does not regard operations for the correction of septal deflections as justifiable, except in the more extreme cases.

Hæmatoma of the nasal septum is described; the treatment laid down, however, is based on the experience of one case only. It is surprising that this affection is not seen more frequently, since blows upon the nose are of constant occurrence.

The author calls attention to the fact that "when the fifth nerve or its nasal branches are injured or diseased, the mucous membrane of the nasal fossæ loses its sensibility." It is unaccountable that he has not availed himself in this connection of the opportunity to draw attention to the probability of more profound disease arising from reflected nervous influences on the nasal cavity than would be implied in the mere loss of sensibility referred to.

The author takes a plunge into the field of otology in respect to "throat deafness," before quite ending his work. Otologists cannot but be gratified that so competent an observer has given his own experience in nasal affections, so many of which are known to frequently affect the ear; but the chapter on "Throat Deafness" consists entirely of citations from the writings of persons conversant with the hearing organ, and the effort to thus place the cart before the horse, so to speak, does not add to the value of Dr. Mackenzie's book. Correctly speaking, "deafness" cannot be regarded as "throat" with any more propriety than uterine reflexes influencing the ear can be said to constitute "uterine deafness." The most important influence of nasal disease and deformities on the organ of hearing are not alluded to, namely, the interference with tympanal aeration. The recommendations in the way of treatment of the ear itself are exceedingly crude, and are mostly at variance with the practice of otologists of the present day.

Reports of Societies.

PRACTITIONER'S SOCIETY OF THE CITY OF NEW YORK.

Stated Meeting, December 5, 1884.

A. B. Ball, M.D., President, in the Chair.

FUNCTIONAL HEMIANÆSTHESIA.

Dr. C. L. Dana presented a patient with functional hemianæsthesia of one upper extremity, and hemiataxia of the lower extremity of the same side. The patient had been referred to him for examination by Dr. S. M. Roberts. Until 1876 he was a perfectly well man, without the history of any specific disease. At that time he was taken, without special cause, with great feebleness in all of the extremities, general paresis. He laid in bed several weeks, without symptoms of organic disease of the spine, and as he gradually recovered symptoms of paræsthesia and anæsthesia developed, and probably some ataxic symptoms, as well as some paresis in the arms and legs, especially affecting the left side. He reached his worst condition in 1878, when he had almost complete hemianæsthesia affecting the left side, affecting the gustatory nerve, but it did not seem to affect any other special sense to any great extent. Concerning the gustatory sense, the chorda tympani only was affected, as the patient was unable to taste anything on the left side of the tongue on its anterior two-thirds, while at the back part of the tongue the taste was unimpaired. Under the use of tonics and the Faradic brush these symptoms nearly all disappeared. The patient had never exhibited any hysterical symptoms. There was no evidence that he had ever indulged in sexual excess, nor had there been evidence of any organic disease. Another attack, similar in character, occurred in 1881, and from that also he was nearly relieved in a few months.

About one year ago the same symptoms returned, and had continued. When Dr. Dana first saw him, two or three days ago, the patient had lost the tactile sense affecting the left hand along the distribution of the median nerve, but not in the line of distribution of the ulnar nerve, and there was paræsthesia also, or a sensation of numbness. There was no ataxia in the hand at all, and he had no loss of pain or temperature sense—simply loss of tactile sense. His left leg showed symptoms of ataxia, and not of anæsthesia. The patient can now distinguish between heat and cold, and feels perfectly the sensation of touch, but he has a peculiar gait, ataxic in character, and exhibited all the tests of the presence of ataxia. His gait was somewhat peculiar, resembling that of spastic paresis in the left leg; that is, he walked with a rigid leg, and dragged the foot somewhat. At the same time, there was no loss of power in the leg. He walked better sometimes than he did at others. Dr. Dana attributed the symptoms to a certain amount of ataxia. The patient had also had exaggerated reflexes and ankle clonus, symptoms which suggested lateral sclerosis, but there were no other symptoms of organic disease.

Dr. Dana regarded the case as one of hysterical hemianæsthesia and hemiataxia, without any symptom of hysteria, and therefore he thought it better to designate the affection as functional hemianæsthesia and hemiataxia.

The patient had been treated by metallotherapy with the use of gold, but without success. He regarded the prognosis as very favorable, so far as nearly complete recovery was concerned.

Dr. Beverley Robinson then read a paper (see page 29) entitled

ON THE UTILITY TO PATIENTS SUFFERING FROM PULMONARY PHTHISIS OF INTRA-PULMONARY INJECTIONS.

Dr. Sexton said that while the paper was being read it occurred to him that the question of hemorrhage was an interesting one, and he recalled to mind several gunshot wounds of the chest which he saw during the late war, and in which, although hemorrhage was great, it seemed that the patients recovered from such wounds better than from wounds of similar gravity in any other part of the body.

Dr. T. E. Satterthwaite said that he had had no experience in the use of intra-pulmonary injections, and therefore his remarks would be simply theoretical. He did not suppose that any definite conclusions could be reached until a much larger clinical experience had been obtained; and even with increased clinical data not very much could be done toward solving the problem, because phthisis pulmonalis tended toward a fatal issue, and but little was known of the natural history of the affection. Dr. Satterthwaite thought, however, that we could reason somewhat by analogy, and was unable to see why the ordinary rules of surgery could not be applied to the treatment of a pulmonary cavity. For, in the first place, there was a certain tendency in pulmonary tissue to cicatrization, and in the walls of a cicatrized cavity miliary tubercles were found. If, therefore, in tuberculous cavities there was a tendency toward cure in that manner, why might not such cavities be treated by processes which tended toward the bringing about of cicatrization. It had been claimed that injections of an infusion of oak-bark into the inguinal canal would produce fibrous induration to the extent of causing a radical cure of hernia, and doubtless there were several substances which would accomplish the same result. It was also well known that by injecting an irritating substance into the tissue of the lower animals fibrous induration of tissue could be produced artificially. If that could be accomplished, why could not something be accomplished in the way of aiding in closing pulmonary cavities? At all events, by injecting certain substances such cavities could be disinfected, and the general condition of the patient might thereby be improved. Whether the putrefying material be removed with the aspirator or disinfected in position was not a question of very much consequence. The cavities in the lungs were real cavities lined with pseudo-membrane, and he was unable to see why granulations might not be stimulated in such cavities, and in that manner the danger from hemorrhage be overcome, because it checked the ulcerative process.

More than that, acute tuberculosis was due to an ulcerative process extending into the lymphatics and veins, and so throughout the general system. He therefore believed that pulmonary cavities, from a theoretical standpoint, could be treated in this manner for the amelioration of symptoms, if for nothing else.

But he would not think so seriously of injecting infiltrated pulmonary tissue, at a period previous to the formation of cavities; for he was unable to see any reason for the use of the injections. However, there might be good reasons for resorting to them, perhaps, and it might be shown that no harm would result; and further, it might be determined, possibly, that the softening process would be favorably affected by their use. He should be inclined to think, however, that it would not be favorably affected.

The quality of the injections was an important consideration. Such substances should be used as did not produce coagulation or granular deposit of any kind. A watery solution of iodine would produce a granular deposit, and this granular deposit would produce miliary tuberculosis. The use of Lugol's solution, as indicated by Dr. Robinson, would overcome this objection. Dr. Satterthwaite simply wished to call attention to the use of substances which would not decompose in any way, and give rise to a granular deposit.

Dr. Kinnicutt had listened to the paper of the evening with much interest. He confessed that the treatment of circumscribed pulmonary *infiltrations* by intra-pulmonary injections was a wholly new one to him. Dr. Robinson had apparently shown that such injections were harmless; much more extended clinical experience was

necessary to demonstrate their *usefulness*. The theoretical arguments against their exerting any curative influence in the lesions described above seemed to him very strong.

The treatment of phthisical *cavities* by intra-pulmonary injections had been shown to apparently produce an amelioration in certain symptoms, viz., cough and excessive secretion; a temporary corresponding improvement in the general condition of the patient apparently followed, and hence such injections might be of service. Dr. Kinnicutt was inclined to believe that more pronounced benefit might be obtained by means of incision and paracentesis, or puncture and free drainage of such cavities. Recent clinical reports had shown that such operative interference was attended with more or less benefit in three classes of cases, viz.: 1, in large phthisical cavities; 2, in bronchiectatic cavities; 3, in abscess and gangrene of the lung.

In the first and second classes many of the worst symptoms were due to septic poisoning, the result of the absorption of residual secretion, which could only be removed by free drainage. In the third class, operative interference was followed in many cases by complete recovery.

Dr. C. L. Dana had taken a great deal of interest in the paper, because he belonged to a phthisical family, and thought that possibly Dr. Robinson might have an opportunity to perform an injection upon him. He desired, however, to impress one particular point alluded to by Dr. Robinson, and that was the lack of success with which so many ordinary cases of phthisis were treated. Under present therapeutical methods phthisis was almost inevitably fatal, and he would be glad to see any method tried which offered new chances for the patient. Perhaps the greatest objection was that it could be only applied in the third or last stage of phthisis, as at that time the prognosis was exceedingly bad, and probably the procedure would not do very much good.

The President thought that Dr. Robinson's paper was virtually a contribution on injection of consolidated pulmonary tissue rather than the treatment of pulmonary cavities, and he would ask Dr. Robinson if any attempt was made in his cases to estimate the size of the consolidated mass.

Dr. Robinson replied that, up to a certain point such an estimate was made; that is, so far as it was practicable.

The President remarked further that his point was that, by resorting to injections of this kind into the consolidated pulmonary mass, the influence which the injection exerted must be very limited, because, if the consolidated mass was very extensive it was hardly probable that the influence of each injection, whatever the substance might be, could extend to any considerable distance beyond the seat of puncture; so that, unless repeated injections were made, he was unable to see how very much effect could be obtained from such a procedure. So far as he had understood Dr. Robinson, the injections were not made repeatedly; that is, not more than an average of two injections in each case. He had had no experience in the use of the remedial measure, and was perfectly willing to accept the results; but at the same time was rather sceptical with regard to the ability to modify a large consolidated mass of pulmonary tissue by injecting it in the manner referred to.

With reference to modifying the condition of pulmonary cavities, that was an entirely different thing. But even there the subject was one of very great difficulty. How we could always guide a needle into a cavity in the lung was a question which the President confessed perplexed him very much. Still further, with a comparatively infrequent injection of disinfected fluid into a large cavity, curative changes would be less likely to be induced than they would be by a more radical procedure.

It should be recollected, therefore, that in the paper there were two problems: one related to the treatment of pulmonary cavities, and the other to the treatment of consolidated or softened pulmonary tissue, and the two problems were entirely distinct from each other. It seemed to him that the burthen of the paper was with regard to the treatment of consolidated or softening tissue, and not chiefly with regard to the treatment of pulmonary cavities; and it was that which distinguished the paper from any contribution which had ever been presented, and also the feature which made it one of very great interest.

Dr. Robinson, in closing the discussion, said with regard to incision and drainage of phthisical cavities, Dr. Kinnicutt had stated that, within some months or years past, certain cavities involving more or less pulmonary tissue had been opened and drained with cure. With these cases he was familiar, and it was to the credit of surgery that the operation had been performed. But he had not read of cases in which a cavity, large or small, in a non-phthisical subject, had been opened and drained with beneficial effects to the patient, and he would not expect this operation, which was one of considerable importance, performed in a phthisical patient in whom a large cavity had already formed, to yield very much benefit. He would also say that after reading Dr. Pepper's contributions he had not been very favorably impressed with the benefits which were likely to follow the injection of pulmonary cavities in an individual who was nearly dead. The object of the method of treatment to which he had resorted was practically to see what could be done without harm in a patient already advanced in phthisis, and it seemed to him that we were authorized to use intra-pulmonary injections where we might reasonably hope to produce some beneficial effect. Practically, he did not believe that cicatrization of the cavities would be produced. In a certain number of cases considerable progress in this direction, perhaps, might be secured; but, as a rule, the abscesses would not be obliterated. Therefore he was not so much convinced of the utility of injecting pulmonary cavities, as of the attempt to try and see what the lung tissue would permit in the way of the use of such measures; and he assumed that, if we could simply relieve symptoms, we should be doing good if it could be done without pain or danger, as it had been proven that it could be. In a certain number of cases symptoms could be alleviated, which was beneficial.

He agreed with Dr. Dana in the statement that he did not see phthisical patients get well, except in rare instances. Personally, he did not believe that cures were of such frequent occurrence as had been claimed. In a few instances when the lung was in the first stage of phthisis, and the patient was so situated that the benefits of treatment and climatic changes could be secured, the patients had recovered, but such cases were only few in number as compared with the great number of fatal cases. Where the softening process had already begun, or cavities had already formed, the great rule was that the patients were not cured, and recovery took place only in exceptional instances. Practically, he regarded all cases of phthisis in which cavities existed as absolutely hopeless. With regard to treatment in these cases, therefore, not very much could be hoped for; but in the method which he had described there was perhaps a grain of hope, at least for the alleviation of symptoms.

With regard to the injection of consolidated pulmonary tissue, he had nothing very much to guide him. He had injected glandular enlargements, goitrous swellings, etc., with considerable beneficial effect, and, reasoning by analogy, he simply believed that if we could inject consolidated pulmonary tissue without manifest harm to the patient, so far as the injections were concerned, we were justified in resorting to these measures whenever that condition existed which would probably go on from bad to worse unless arrested. Dr. Robinson then read the history of one or two cases.

Dr. Kinnicutt begged to offer a single criticism on

the analogy which Dr. Robinson had drawn between goitrous tumors, glandular enlargements, and phthisical infiltrations. Dr. Robinson had apparently wholly overlooked the very different etiology of these affections. If we accept Koch's theory of phthisis, that the tubercle bacilli precede in time and place all the pathological changes peculiar to tuberculosis; and that their number, appearance, and disappearance stand in direct relation to the course of the tuberculosis, it was quite impossible to believe that these bacilli could be destroyed, and the pathological changes thereby be effected, by the injection of such solutions as Dr. Robinson had employed.

Dr. Robinson was not aware that the etiology mentioned by Dr. Kinnicutt, as such, had been accepted by general admission. He had simply hoped that by some procedure we might reach ultimately definite conclusions concerning the benefit to be derived from this method of treatment.

The Society then adjourned.

Correspondence.

STATEMENT OF THE SIGNERS OF A CHARGE AGAINST A FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

On November 20, 1884, a document, of which the following is a copy, was sent to the New York Academy of Medicine:

We hereby transmit to the "New York Academy of Medicine," in accordance with Article XIV. of the by-laws of the Academy, the following charge and specifications against Fordyce Barker, a Fellow of the Academy:

Charge.—That Fordyce Barker, Fellow of the New York Academy of Medicine, has violated section 3 of Article XIV. of the by-laws of the Academy, which reads:

"It shall be a chargeable offence . . . or to commit any act which unfavorably affects the character of the medical profession."

Specification 1.—On or about January 4, 1854, or at some date later than January 4, 1854, the said Fordyce Barker did, with his own hand, inscribe in the Signature Book of the Academy the statement that he was a graduate in medicine of Paris, of the date of 1844, the said Fordyce Barker not being at that time or at any subsequent time a graduate of Paris.

Specification 2.—On or about October 4, 1880, the said Fordyce Barker did register in the book of registry for physicians, in the office of the Clerk of the city and county of New York, that he was a graduate in medicine of Paris of the date of 1844, the said Fordyce Barker not being at that time or at any subsequent time a graduate of Paris.

Specification 3.—That on divers occasions and in divers places in the State of New York the said Fordyce Barker has practised medicine in violation of chapter 513 of the laws of 1880 of the State of New York.

Specification 4.—That on or about October 4, 1880, the said Fordyce Barker did appear before one C. M. Smyth, Commissioner of Deeds, and did make an affidavit that he, Fordyce Barker, in the year 1844, received a diploma granted by the École de Médecine, Paris, France. And deponent further says, that by authority of said diploma he has been practising medicine since the year 1844, and that in making such affidavit the said Fordyce Barker has violated that portion of section 2, chapter 513, of the Laws of 1880, which reads as follows:

"The person so registering shall subscribe and verify by oath or affirmation, before a person duly qualified to administer oaths under the laws of the State, an affidavit containing such facts, and whether such authority is by diploma or license, and the date of the same and by whom granted, which, if wilfully false, shall subject the affiant to conviction and punishment for perjury." . . .

The subscribers pray that the above charge and specifications shall be referred by the Academy to the Committee on Medical Ethics, according to the provisions of Article XIV. of the by-laws, and that the said committee shall duly investigate the said charge and specifications, and shall report the decision thereon to the Academy at a stated meeting.

The subscribers also pray that they be allowed to appear before the Committee on Medical Ethics to support the charge and specifications made by them against Fordyce Barker, together with papers, documents, and witnesses.

Edmund S. F. Arnold, M.D.
Nathan Bozeman, M.D.
Austin Flint, Jr., M.D.
S. S. Purple, M.D.
C. S. Wood, M.D.
William Young, M.D.

In due time, the accusers, signers of this document, were cited to appear before the Committee on Medical Ethics, of the Academy, and did so appear, with Dr. William T. White as a witness, on Wednesday, December 3, 1884, the accused not appearing either personally or by representative.

In support of Specification 1 the accusers presented a transcript from the signature-book of the Academy, of which the following is a copy:

Autograph Registry in the Signature Book, New York Academy of Medicine.

Name ..... Fordyce Barker.
Number ..... 332.
Date of signing ..... January 4, 1854.
Graduate of ..... Bowd. Coll., 1841, Paris, 1844.
Nativity ..... Maine.

In support of Specification 2 the accusers presented a copy of "Registered Physicians in the County of New York," showing the following:

Barker Fordyce, 24 East 38th, École. de Méd., Paris, France, 1844.

In support of Specification 3 the accusers stated the well-known fact that Dr. Fordyce Barker is and has been for many years a practitioner of medicine in the city of New York.

In support of Specification 4, the accusers presented a certified copy of an affidavit reading as follows:

State of New York, City and County of New York, ss.:

Fordyce Barker, being duly sworn, deposes and says that he resides at No. 24 East Thirty-eighth Street, in the city of New York, and was born in the State of Maine. And that in the year 1844 he received a diploma granted by the École de Médecine, Paris, France. And deponent further says that by authority of said diploma he has been practising medicine since the year 1844.

Fordyce Barker.

Sworn to before me, this 4th day of October, 1880.
C. M. Smyth, Commissioner of Deeds, N. Y. C.

Affidavit of F. Barker, practising medicine. Filed October 4, 1880:

State of New York, City and County of New York, ss.:

I, Patrick Keenan, Clerk of the said city and county, and Clerk of the Supreme Court of said State for said county, do certify that I have compared the preceding with the original physician's affidavit on file in my office, and that the same is a correct transcript therefrom and the whole of such original.

In witness whereof I have hereunto subscribed my name and affixed my official seal, this fourteenth day of January, 1884.

(Seal.) Patrick Keenan, Clerk.

In further support of specification 4, the accusers presented documents, of which the following are true translations, the translations being verified, as read, by the Chairman of the Committee on Medical Ethics, from the original documents:

(A.)

Chamber of Deputies. Paris, December 24, 1883.

Sir: M. Clemenceau, who is prevented at this time by many occupations, has requested me to transmit to you the three accompanying papers, which answer the inquiry of your letter of the month of May last.

As you can judge, the investigations concerning M. Fordyce Barker, and made by M. Ch. Robin, Professor at the Faculty of Medicine of Paris, have given only a negative result.

The name of M. Barker does not appear upon the registers of the Faculty of Paris.

Be pleased to receive, sir, the assurance of my most distinguished consideration.

Secretary of M. Clemenceau.
(Signature.)

(B.)

Faculty of Medicine of Paris.

Request to the keeper of the archives to please to communicate to me the following documents:

The register of Mr. Fordyce Barker, or B. Fordyce Barker, or Benjamin Fordyce Barker.

Secretary of the Faculty.
(Signature.)
Paris, June 16, 1883.

Not in the archives.

C. Chevallier.

(C.)

The tables of theses from 1840 to 1845, inclusive, have been looked through; all the papers complete and incomplete of doctors and even of officers of health of these six years have been examined and the name asked for has not been found, neither Barker, nor Fordyce, nor Benjamin. C. CHEVALLIER.

In the letter marked (A) were inclosed the documents (B) and (C). The third inclosure mentioned was simply a personal card from Professor Robin to M. Clemenceau, which was shown to the Committee, and recognized by the Committee as unimportant.

Translation of a letter (D) from Professor Charles Robin, Member of the Institute (Academy of Sciences), Professor of Histology at the Faculty of Medicine of Paris, and the Academy of Medicine, and Life Senator of France:

(D.)

[Senate.] PARIS, February 10, 1884.

MY DEAR FLINT: I address you with this, the result of the investigations made at our Faculty. We find no trace of examinations undergone or of a thesis defended. It could have been obtained by equivalence of previous studies, not to undergo an examination, which is, indeed, very rare, but then it would be an indication of a defence of a thesis, and this should be in the *Collection of Theses* under its number of order. There is no trace of this. It would be very astonishing, on the other hand, that M. Barker has not preserved, and is not able to show to his compatriots, a copy of this thesis; for there is no doctorate here without a thesis, and in the absence of a certificate of defence of the thesis, the putting in evidence before whom it was that the *brochure* in quarto, in which form it is printed and defended, is the only proof that it really has been defended. If one cannot present this printed thesis, or at least a certificate of defence, with a stamp like that which is added here, or finally the *diploma* printed on parchment, one is not a doctor of Paris.

In the case in which a foreign doctor obtains the authorization to practise in Paris, he would be able to show the certificate of authorization, and the archives of the school would preserve the mention of this authorization, of which there is not a trace.

Receive, I beg, the expression of my best and devoted remembrances and of my most cordial friendship. C. ROBIN.

In the letter marked (D) the following was inclosed:

(E.)

FACULTY OF MEDICINE OF PARIS,
[Seal.] PARIS, February 7, 1884.

It results from the prescribed investigations of the archives and at the library of the Faculty that no trace exists of the medical studies that have been made in Paris by Mr. Barker or Fordyce or Benjamin from 1840 to 1870.

It is not possible that a foreigner should have received a diploma of doctor of medicine unless his name be inscribed in the archives.

The accusers also presented in evidence a copy of Chapter 513 of the Laws of 1880.

Dr. William T. White, who was presented as a witness, testified before the Committee that, in the spring of 1884, he had written to the Secretary of the Faculty of Medicine of Paris, giving a list of names of certain persons registered in the office of the County Clerk in New York City, who claimed to be graduates of Paris, and asking a report thereon. He exhibited this report, which was signed by C. Chevallier, which report showed a note opposite the name of Fordyce Barker, indicating that the said Fordyce Barker was not a graduate of Paris. Certain of the persons whose names had been sent to Paris by Dr. White were acknowledged as graduates of Paris, and others were indicated as not graduates of Paris. Among those marked as not graduates of Paris, was the name of Fordyce Barker.

In answer to a question by the Committee Dr. White testified that, shortly after he had received the report from Paris he had called upon Dr. Barker, as a committee from the New York Medico Histological Society, and had inquired with regard to his alleged graduation at Paris. Dr. Barker, in this interview, did not present any documentary evidence of his graduation at Paris, and told Dr. White, in substance, that he might put his name in the "Medical Register" as a graduate of Paris, or not, as he saw fit.

In answer to questions by the Committee, one of the accusers gave a full account of the procuring of the documents from Paris. He also stated that a personal and professional friend of the accused had written to him while he, the accused, was in Europe, in April, 1884, inclosing copies of documents (B), (C), and (E), urging him to go at once to Paris and obtain written vindication, and then to return home as soon as possible and set himself right; that he had seen an acknowledgment of the receipt of this letter from the accused, but had not heard of any explanation or vindication presented by him.

The accusers, after this meeting, made a written demand on the Committee, that they have the right to appear at any and all of their meetings at which the accused was cited to appear.

The accusers, with the exception of Dr. C. S. Wood, again appeared before the Committee, on December 10, 1884.

The Committee then read a written defence sent by the accused, with letters from Dr. E. H. Davis, and Dr. R. Ogden Doremus. Copies of these documents were not furnished to the accusers. The following is an abstract of the report of the Committee to the Academy, presented December 18, 1884, taken from the *New York Daily Tribune* of December 19, 1884:

REPORT OF THE COMMITTEE ON ETHICS.—Dr. Smith's reading of the report of the Committee on Ethics was punctuated with applause at every place favorable to the Academy's chief officer, and it showed increased fervor each time. The report took up the charges and specifications in detail and found the sole evidence against the claim of Dr. Barker to a Paris diploma, rested on the fact that the proper Paris records were silent on the subject. It declared that the statement in the signature book of the Academy of 1854 was evidently written in, and called attention to the fact that Dr. Barker applied for fellowship in the Academy as a graduate of Bowdoin College. The report then presented Dr. Barker's explanation of how he obtained the Paris diploma. In brief, it showed that he had studied at the École de Médecine in 1845, was called home by illness in his family before receiving a diploma, visited Paris in 1861, and through a conversation at a dinner with Professor Trousseau, of Paris, and the Minister of Public Instruction, learned that the school had issued him a diploma, which he received a few days afterward from M. Trousseau.

Dr. Barker was unable to produce his diploma, as he lost it among others when he removed from his home in Union Place to Madison Avenue in 1862.

TESTIMONY OF DRS. DAVIS AND DOREMUS.—In corroboration of his statement, the Committee's report continued, Dr. Barker produced letters from Dr. Edwin H. Davis and Professor R. Ogden Doremus, who were present, among others, at a gathering of friends who greeted Dr. Barker upon his return from Paris in 1861, and to whom he showed the diploma of the École de Médecine. The reading of these letters, which were dated last November, and which recalled the occasion by a dozen incidents and features, set all the physicians to clapping their hands vigorously. In conclusion the Committee reported that they could not offset the testimony of Dr. Barker and these two other witnesses with the defectiveness of public records, and they accordingly found the charges not sustained.

The Committee before whom these proceedings were held was constituted as follows: Dr. A. H. Smith, *Chairman;* Dr. C. D. Varley, *Secretary;* Dr. V. P. Gibney, Dr. H. E. Crampton, and Dr. C. A. Leale.

At a meeting of the New York Academy of Medicine, held December 18, 1884, the report of the Committee was adopted.

The signers of the charge and specifications desire to place before the profession, without comment, the proceedings of the Committee as fully as they are able to present them. At neither of the two meetings of the Committee, at which they were present, did Dr. Barker or Drs. Davis and Doremus personally appear. It is proper to add, also, that at no time during either of the two sessions of the Committee did the members thereof call in question the authenticity of the French documents or the accuracy of the translations. At the close of the second meeting the members of the Committee all stated to the undersigned that they admitted that the documents presented by them were genuine.

NEW YORK CITY, December 29, 1884.

A STATEMENT FROM THE COMMITTEE ON ETHICS OF THE ACADEMY.

To the Editor of The Medical Record.

Sir: As the report of the proceedings of the Academy of Medicine at the session of December 18th, as contained in The Record (the only report given by the medical press), does not show the character of the evidence upon which the Committee on Ethics based their decision in the case of Dr. Barker, it is only just that the following extracts from the Committee's report should be given to the profession through your columns, although it appeared in the New York *Tribune* of December 19th:

"The defence of Dr. Barker consists in a clear and dispassionate statement, in which the following points are maintained:

"That in 1845, at the suggestion of friends in Paris who were members of the Faculty, he underwent examinations in a number of departments with the intention of taking a degree from the School of Medicine.

"That his studies and examinations were interrupted by his being called home on account of the alarming illness of his wife's mother.

"That while awaiting a steamer in which to return he received a letter from Professor Orfila, Dean of the Faculty, informing him that a diploma would be granted him at some date in the near future, and that he replied to this note, stating the necessity for his immediate return home, and relinquishing his claim to the diploma, as he could not comply with the necessary conditions.

"That sixteen years after, in 1861, not having in the meantime heard anything further about the diploma, he was dining in Paris with M. Trousseau in company with the Minister of Public Instruction, when Trousseau publicly referred to his (Dr. Barker's) being a graduate of Paris. That he immediately disclaimed the title, and related the facts above stated, upon which Trousseau affirmed that he knew that a diploma had been made out for Dr. Barker, as he himself had taken a special interest in it, and that the diploma must be somewhere in the Department of the Minister of Public Instruction, and appealed to that officer, who was then present, to have it searched for.

"That a few days later, returning from a temporary absence from Paris, he found at his hotel a roll addressed to M. Trousseau, and marked as coming from the Minister of Public Instruction, and which contained his diploma from the School of Medicine in Paris, dated in 1845.

"That on his return home, on the evening of his arrival in New York, he showed this diploma to a number of his friends gathered at his house to welcome him, two of whom are still living and remember the occurrence.

"That some years later it was discovered that this diploma, with all his diplomas received prior to 1862, was lost, presumably on the occasion of his removal from Union Place to his house in Madison Avenue.

"This statement from a man of the high character of Dr. Barker, coupled with the fact that he did not claim that he had a Paris degree until his return from Paris in 1861, and when he had already been twenty years in practice, during sixteen of which he had been a professor, and when he had been the recipient of many professional honors, among them the vice-presidency of the Academy and the presidency of the Medical Society of the State of New York, and when a Paris degree could add nothing to his reputation, might well be deemed a sufficient answer to mere negative evidence depending for its validity upon the assumption that a record cannot be incomplete.

"But in addition to this there is the evidence of two well known gentlemen who remember seeing and examining the Paris diploma, and who recall different incidents in connection with the occasion which place the accuracy of their recollection beyond a possibility of doubt. Both these letters show that the writers not only remember the diploma, but that their attention was arrested by the difference between its date and the time of its reception. The committee thus finds itself called upon to weigh the negative evidence of the records whose general accuracy and completeness they have no means of estimating against the positive testimony of three unimpeachable witnesses.

"It is the unanimous decision of the committee that the witnesses must be believed as against the negative inference from the records, and that the charge and specifications are not sustained."

The following are the letters referred to above:

November 28, 1884, Tuesday evening late.

My Dear Doremus: Will you kindly answer for me within a day or two as a personal favor, the following questions: 1. Do you remember to have ever seen a diploma of Doctor of Medicine for myself, which I brought from Paris? 2. Can you recall what year you saw this, and any circumstances in connection with my showing it to you which fixes the time in your mind? 3. Do you recall the date of the diploma, and if so whether it was the same year that the diploma was shown to you? 4. If it was not the same year, can you remember any explanation given by me why I had not before received it? 5. Do you chance to remember any of the signatures of the diploma or anything in connection with its general appearance? 6. If you recall any of the above points, do you remember of any conversation with me since you saw my diploma from Paris either in regard to this or any other diploma of mine? Will you kindly send back this note with your reply.

Ever faithfully,

Fordyce Barker.

Answer.

My Dear Doctor: Although it is many years since and we both have seen many changes, I remember the diploma you refer to, and will answer your questions seriatim.

I fix in my mind the year 1861 by the following associations: in the spring your health was such as to cause great anxiety on the part of all those who loved you. You left early in May, I think, for Europe. During your absence we learned that by the advice of your medical friends you were passing the summer at Ems While you were away our daughter was born, the only child that we have that we had not had the comfort of your presence at the birth. The battle of Bull Run occurred while you were away, in which General Tyler had so prominent a part, and I remember how we talked and thought of what your interest would be in reading about it. The evening of your landing there was a merry gathering of friends at your house, to welcome you home, but I only especially recall Mr. Osborn and Chas. Budd, the latter by his funny suggestion as to your diploma. You told us of your summer, and the kindness to you on the part of your medical friends, especially Sir Joseph Olliffe and M. Trousseau. Through your cordial introduction to both of these distinguished men my wife and myself were favored with their acquaintance in 1862 and 1863 while residing in Paris, and both of them were most generous in their medical advice to her. It was in connection with M. Trousseau you showed us your diploma. My impression is, you said that he had got it for you, and you pointed out that it was dated in 1845. I remember that you explained that you were to receive it in the year of its date, but you were called back to this country by the dangerous illness of cousin Lizzie's mother. I do not remember the particulars as to how Professor Trousseau then got the diploma for you. I remember that Charlie Budd suggested that you should have it framed and hung in glass on the gate of your yard, and I proposed in addition that you should also have your Greek diploma with its golden printing and the translation by Dr. Hawks hung up—then it now strikes me that Dr. Hawks was present at the time. I do not recall any special feature of the diploma, except the name of Orfila-Doyen, for I was familiar with his toxicological works. I do not remember that we have had any conversation about your diploma since that time, except that I have a vague recollection of having heard you say that some way you had lost all your diplomas. I think it was when you moved from 70 Union place, as my wife lost a trunk of valuable letters some years later, through a careless or wicked cartman. Your particular regret was the loss of the Greek diploma, as it would have been a unique curiosity as an heir-loom in the family of your descendants. I am sorry if my memory fails me in other details which you may wish to have, but my dear old friend in twenty-three years many things pass out of our minds which greatly interest us at the time of their occurrence.

Yours most cordially,

R. Ogden Doremus.

Tuesday Evening.

Dear Doctor Davis: You live so far from me and I am worked so hard that it is difficult for me to make the time to visit you. I therefore write you on a matter that may be of some personal interest to me. Do you chance to remember of my showing you some twenty or more years ago, a diploma of Doctor of Medicine for myself from the Faculty of Medicine of Paris, which I had just brought home from Europe, although the diploma was dated fifteen or sixteen years before. If so, will you do me the kindness to write me a few lines to tell me what you recollect about it, when it was, who were present at the time, and any other incidents in connection with this, that on reflection may come back to your mind. Of course, after such a lapse of time, it is not to be supposed that you can recall minute details, general facts is all that I wish, and I will ask you to return note with your reply.

Ever faithfully yours,

Fordyce Barker.

Answer.

New York, November 28, 1884.

Dear Doctor: I reply with pleasure to your note. I do recollect that you showed to several of your friends a diploma of Doctor of Medicine, which you had brought from Paris and which was dated in 1844 or 1845. Several friends had called to welcome you home from Europe, the only ones I now recall were Dr. Doremus and Dr. Charles Budd. I think it must have been in 1861, because I am quite sure that you described your feelings in coming up from the steamer and meeting on Broadway a regiment marching down and singing "John Brown." I remember examining the diploma with some care, because for more than ten years I had a good deal to do with the getting up of diplomas for our old college. I only remem-

ber Orfila as one of the signers, because his name was familiar to me, and also that it was signed by the Minister of Public Instruction, but I have forgotten his name. I remember also that you gave an explanation of the reason why you had not received it at its date, but I have forgotten what this explanation was. I also recall the fact that the name of Trousseau was written on the back, and that you said that Trousseau had got it for you. I also recall the fact that Doremus and Budd made some joking suggestions as to what you ought to do with the diploma, but that you seemed to think the diploma of M.D., dated so far back, would not be of much value in making practice or reputation, as you had received several others since from learned societies. I am sorry that I cannot remember more of the particulars. I wish we could see more of each other as in old times.

I remain ever your friend,
EDWIN H. DAVIS, M.D.

I would call attention to the language of Professor Robin in his letter to Dr. Flint (read before the Academy), in which he enumerates the evidences of the possession of a degree from Paris, any one of which he would consider conclusive. He says: "If one cannot present this printed thesis, or at least a certificate of defence, with a stamp like that which is added here, *or finally*, the diploma printed on parchment, one is not a doctor of Paris."

Now the *finality* accepted by Professor Robin is exactly what these letters of Drs. Doremus and Davis prove that Dr. Barker did actually present.

In the light of the evidence no fair-minded person can affect to doubt that a diploma was prepared for Dr. Barker in 1845, but not then registered as it was not then called for; and that in 1861 this old diploma, whose requirements had now become obsolete in view of the position Dr. Barker had attained, was, as a matter of compliment, simply passed over to him, without the formality of registration, or perhaps failed of registration through remissness of the registrar.

It is unnecessary to remark that the full report of the Committee, including all the documents presented by the accusers, is copied into the minutes of the Academy, and is open to the inspection of any Fellow who may not be satisfied with the published statements.

ANDREW H. SMITH, M.D.,
Chairman Committee on Ethics.

CANADA CORRESPONDENCE.

(From our Special Correspondent.)

DOMINION HEALTH BUREAU — ONTARIO MEDICAL ASSOCIATION — COLLEGE OF PHYSICIANS AND SURGEONS, ONTARIO—ACTINOMYCOSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: For some months past there has been some agitation to establish a Department of Health for the Dominion. The scheme is not yet matured, and what shape it may finally take is uncertain. It is proposed to place this new departure under the control of the Minister of Agriculture, who shall have cognizance of quarantine, statistics, and other questions that may come under Federal control. It is proposed that there be a Deputy Minister of Health, and a secretary, both of whom are to be medical men. There is some fear that this Dominion Board of Health may conflict in its working with the provincial boards already established, or such as may yet be organized. There need be no real fear on this ground, however, as there is abundance of local and general health matters to deal with to open up a wide field of usefulness for both the local and central boards. This sanitary committee is to be associated with the Minister of Agriculture, and give advice on matters of public health. The members are to be appointed by the Government so as to represent the different provinces. The chairmen of the provincial boards, and, in cases where there is no provincial board, the chairman of the principal city board will probably be *ex officio* members of this Sanitary Committee.

The Ontario Medical Association held its annual meeting in Hamilton on the 4th and 5th of June, under the presidency of Dr. Daniel Clark, Superintendent of the Asylum for the Insane, Toronto. In his address he dwelt ably and eloquently on the great progress that medical education had been making during the past years in this country, and on the much more efficient state of the medical colleges. He then referred to certain kinds of advertisements in both religious and secular papers. He thought that these have a very degrading influence on the young, and are misleading in the highest degree to persons of weak mind. Many of the advertisements were positively criminal; and it was to be hoped that the day had come when at least the religious press would see its way clear to the sacrificing of a small portion of its income from these sources for a higher standard of morals and honor. Your correspondent would suggest that no higher and nobler work could be undertaken by medical societies than that of arousing public attention to such questions.

The College of Physicians and Surgeons, Ontario, is the real licensing body for the province, as without its diploma practice is illegal. A university degree does not entitle the holder to registration. British degrees and diplomas are only recognized in the event of their being registered in Britain, and it is this certificate of registration that is admitted here. The council of this college is representative of and elected by the qualified physicians of Ontario. During the session, held early in June, it was enacted that every student must attend lectures for a period of four winter sessions of six months each. It was agreed to ask the Legislature for power to appoint a medical practitioner in each electoral division, who shall have a right to tax all medical bills that may be under dispute, and referred for his decision; and that such decision have the same authority as the taxation of bills by the master of the legal profession.

Actinomycosis has been carefully investigated by Dr. Duncan, of the Veterinary College, in Toronto. The disease is produced by a vegetable parasite or fungus, known as the actinomyces. The peculiarity of this fungus is the constantly radiating character of its filaments. The disease exists both in man and the lower animals, being due to the fungus in both cases. The true nature of this disease was first recognized by a veterinary surgeon in 1868. In 1878 Israel discovered it in man. In the ox the lower jaw is principally affected, tumors of various sizes showing themselves, which ultimately break down and discharge. A little of this discharge, without staining, placed upon a slide, and examined with a low power, will usually reveal the radiating fungus in great abundance. In man, in place of the tumors, there are foci of suppuration, in various regions, as dental and iliac abscesses, purulent pleurisy, etc. About fifty per cent., under proper treatment, recover. This consists in opening the abscesses, removing the fungus, and cauterizing the part. As occurring in man, there are twenty-eight cases on record; none in England or America. The disease is comparatively common among cattle. Dr. Duncan first described it among Ontario cattle last November, and pointed out its possible communicability to man.

NORTH CAROLINA CLIMATE FOR CONSUMPTIVES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Since the publication of a communication on the climate of this region in THE MEDICAL RECORD for September 27, 1884, so many letters have been received from physicians having patients in need of such a climate that this means is taken to give further information on the subject. In the published letter referred to above, the reader will find a statement, in tabular form, of the mean temperature at Asheville as compared with resorts in Europe noted for their mild and healthful climate.

One of the most desirable features of this climate is the dryness of the atmosphere. The rainfall for the year

is small, and the distribution throughout the year is all that could be desired; the proportion of rain falling in the various seasons could hardly have been arranged better for the growth of vegetation and the health and comfort of the residents. An important fact regarding the rainfall, and one noted by no other writer to my knowledge, is that of the forty and two-tenths inches for the entire year, but nine and five-tenths inches of water is precipitated during the winter months; while during the summer months, when the evaporation is greater, and when it is needed most to prevent dust and promote the growth of vegetation, there is a fall of thirteen and five-tenths inches. And this is a fact of no little importance to the phthisical or asthmatic invalid.

In the table given below it will be seen that Asheville compares most favorably with the resorts in the south-eastern portion of the United States. The figures for Aiken, Atlanta, and Jacksonville are from Parkes' "Manual of Practical Hygiene" (Wm. Wood & Co.), and it is to be hoped that in the next edition of that very valuable work the climate of Western North Carolina will receive the mention which it deserves. Atlanta being but seventeen miles from Aiken, the statistics of temperature and rainfall of that city are given, since those of the latter place are not at hand.

	Temperature.	Rainfall.			
	Year.	Jan.	Feb.	March.	Year.
		Inches.	Inches.	Inches.	Inches.
Asheville	55.3	2.4	4.4	3.8	40.2
Aiken	62.1	....	....	....	....
Atlanta	....	8.35	10.41	10.98	62.7
Jacksonville	70.1	....	....	....	65.51

The rainfall for the winter months in Asheville is but 13.5 inches, while that of Jacksonville, Fla., is 29.74 inches.

It is worthy of note that the atmosphere in this region, before and after a shower, feels perfectly dry; indeed, the absorbing powers of the soil are so great, and the drainage so perfect, that one can sometimes go for a walk very soon after a heavy shower without muddying his shoes at all.

Physicians do not, as a rule, sufficiently impress upon patients, whom they recommend to the mountain regions, the importance of taking daily exercise in the open air; which is the only way they may obtain the full benefit of the climate. Such advice before they leave home is very important, because the patients possess more confidence in their home physician than they can possibly have in a stranger; and because, without such advice, they too often go to a health resort to wear uncomfortable, fashionable clothing, and in many instances attending balls and parties, becoming over-fatigued and injured by inhaling the hot, impure air of the ball-room. Some sit in the lobby of the hotel much of the time, thinking about their condition or comparing notes with others suffering similarly. This is all true, it has been witnessed repeatedly by the writer.

Cases of incipient phthisis are of course referred to, for those in the last stage should not be sent away from home at all.

It is undoubtedly true that almost any patient in the early stage, who will come to this region and take every possible advantage of the climate, may recover entirely. The best plan is for the patient to bring a loose, comfortable, woollen suit, one which will not be injured by riding horseback, walking, or climbing the hills; and these several forms of exercise should be indulged in daily according to the strength of the patient.

Patients are too apt to over-do at the outset, they feel the stimulation of the mountain air and mistake it for strength, and consequently suffer from becoming over-fatigued. The amount of exercise should be prescribed definitely by the physician, just as he would prescribe the quantity of cod-liver oil, syrup of hypophosphites, or what not.

In advising exercise much stress should be placed upon cumulative exercise, beginning with moderation and very gradually increasing the amount. The patient will improve more steadily, and the gain will be more permanent if he will walk, for instance, three hundred feet the first day, four hundred feet the second, five hundred the third, and so on, until he is able to walk several miles. It is on the principle of the boy lifting the calf every day until it becomes an ox.

As illustrating what has been accomplished in this climate, the following case may be of interest to the profession. The main points will be stated briefly.

In September, 1878, Mr. H——, of Michigan, suffered from hemorrhages from the lungs, and they continued for three months; so frequent and profuse were they that he was reduced in weight from 185 to 103 pounds. He went to Colorado and travelled through the mountains, with the effect of growing worse instead of better. He then came to Asheville, and by riding in the saddle daily, rain or shine, gained rapidly in flesh, was relieved of the cough, night-sweats, and loss of voice. In three months, after having gained twenty-four pounds in weight, he returned to his northern home. But he soon saw that he was growing worse, and, though so weak from renewed hemorrhage that he had to be helped into the saddle, he started to ride the one thousand miles or more on a mustang pony. He accomplished the journey in thirty days, gaining ten pounds of flesh on the way. After reaching Asheville again he was in the saddle every day in all weather, gaining steadily and permanently. So complete and permanent was his recovery that, in the military tournament held in Raleigh not long since, he marched eight miles through the hot dusty streets, and at night slept on the ground rolled in a blanket, without injury.

This case is probably, in some respects, without parallel; especially as regards the excessive hemorrhages, the great and rapid loss of flesh, such persistent exercise on horseback, and rapid and permanent recovery.

Edward A. Gatchell, M.D.

Asheville, N. C.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 28, 1884, to January 3, 1885.

Girard, A. C., Captain and Assistant Surgeon. Ordered from Department of the Missouri to the Department of the East. S. O. 304, A. G. O., December 29, 1884.

Ewing, Charles B., First Lieutenant and Assistant Surgeon (Fort Stanton, N. M.). Granted leave of absence for two months. S. O. 304, A. G. O., December 29, 1884.

The Administration of Alcohol to Parturient Women.—Dr. Heywood Smith, in the *Medical Press*, December 3, 1884, objects to the too frequent use of alcohol in pregnancy, parturition, and childbed. He considers its indiscriminate employment an unmitigated evil, fraught with grave results both near and remote. He admits, however, that in particular instances alcoholic beverages may be used for medicinal purposes. The picture he draws of British women who, during the parturient stage, are more or less under the influence of liquor in some form or other, is a rather sad and repulsive one. Fortunately it has but a very limited applicability in our own country, where the bad habit of excessive alcoholic indulgence in parturient women is seemingly much less prevalent than in Great Britain.

FORCING WITHOUT FEEDING.—In the *British Medical Journal* there are some timely words on this topic, that are applicable to our own country in almost the same measure as to England. Mental power is brain-function as truly as manual power is muscle-function. The brain is as much part of the body as the hand. If the body be weak from lack of feeding, the strength of the limb fails. If the body be weak from lack of feeding, the strength of the brain fails. In the one case manual power is lessened; in the other, mental power is reduced. The underfed can neither lift a heavy weight nor perform a relatively difficult or energetic act of cerebration. All this seems wonderfully simple; but, strangely enough, the authorities concerned in education appear to forget it. Attempts are made to cultivate the brains of growing children by instruction, while their little bodies are insufficiently fed, or, more accurately, half-starved. Surely the great and persistent efforts which have been made to inform public opinion on this initial principle in the physiology of life and activity have not been wholly wasted; and yet it seems as though they had been, when we find the State and the community committed to a policy of forcing without feeding. We are bound by every consideration of duty and interest to undertake the education of the lower orders of the rising population, but it is folly to carry out the enterprise at the expense of the stock we are seeking to cultivate. What would be thought of the gardener who busied himself with the top of a plant, budding and training, without taking the trouble to see that its root was firmly bedded in good soil, and that it had an ample supply of nutriment? The first thing that his master would do on becoming aware of his neglect or imbecility, would probably be to expel him from the nursery. He would be judged unfit for his task. This, however, is precisely what we are running the risk of doing with the young of our nation. We are cultivating their heads, while the organic necessity of eating and drinking is largely disregarded. If the little brain can be brought under the operation of the educator, the body of which that brain is a part may, many people seem to think, be left to take its chance. What makes the matter worse than it might otherwise be, is the fact that we are not simply or solely spending our thought for nought, because good mental work can never be got out of half-starved brains, but we are robbing the other parts of the body by drawing what little energy there may be to a single organ, that of the mind. Only one issue is possible; unfortunately for our race, it cannot be demonstrated until the next generation; then, however, the fatuity of a policy which under-estimates physical needs will stand confessed. The children of the children we are now forcing without feeding, must inevitably be deficient in muscular and general power and vitality. It is needless to write warmly on this point. We are plainly stating a proposition founded on inexorable laws of life and development. Setting aside all questions of immediate consequences, such as the breakdown of overtaught children in board-schools, as to which there is probably much exaggeration in particular cases, we have to face the fact that, by and by, when we are dead, the effects of our economic blunder will begin to make themselves apparent. This consideration should not be wholly disregarded. Meanwhile, although Mrs. Partington could not sweep back the Atlantic with a mop, it is within the reach of everybody to do something toward the mitigation of the mischief in progress. Let a determined endeavor be made to feed the poor little children who are subjected to an unwise and short-sighted policy of starvation and education. It would be difficult to name a more excellent enterprise in the interests of domestic life, now and in the future, than that of the organizations which have been formed to provide the children of the poor with good dinners. Money expended in this way will do more real good than is generally accomplished by indiscriminate charity. The New York Diet Kitchen Association is making some praiseworthy efforts in the direction indicated. But the membership of that young society is far too limited to insure adequate funds for carrying out its objects on a large scale.

WHAT IS THE SOURCE OF UREA.—A correspondent from Washington, D. C., writes us regarding this subject and quotes a statement made by Dr. James Tyson to the effect that "We *now know* that urea is derived almost entirely from the food which is eaten. The old view was that it was the result of the wear and tear on the tissues. But just as the ashes of a steam-engine are derived from the fuel put into the fire-box, so is the urea derived from the food placed into the stomach." Our correspondent doubts the correctness of this statement and asks what are the most recent views. [To this we would say that the most recent views regarding the origin of urea are that it is not formed in the kidneys to any extent; that in fevers and in fasting animals most or all of the urea is the product of tissue waste; that in health the larger part of urea comes from the decomposition of proteid food, the process taking place chiefly in the liver and spleen. The excretion of urea is affected much more by diet than by exercise or other agencies.—ED.]

A CASE OF ECHINOCOCCUS OF THE NECK.—The patient had noticed an enlargement of the neck, principally on the left side, from his earliest youth. About ten years ago, after forced yawning it increased rapidly in size, so that a considerable tumor developed behind the sterno-cleido-mastoid muscle, which caused difficulty of breathing, and was diagnosed by various physicians as struma. On August 20, 1882, Dr. Lindpainter, of Munich, was called to perform the operation of tracheotomy on account of the difficulty of breathing. He found on the left side of the neck a tumor the size of a man's fist, reaching from the clavicle to the ear. The trachea was forced over to the right, and flexed so that respiration was exceedingly difficult, and the œsophagus was also so much compressed that fluids even could only be swallowed with difficulty. Dr. Lindpainter took the tumor for a solid struma, calling for tracheotomy, but upon examining more closely he discovered in a small spot above the clavicle distinct fluctuation. After puncture and the evacuation of about 3 c.c. of clear watery fluid, fluctuation was noticed in another part; he punctured this also, and let out about 5 c.c. of similar fluid, after which the trachea straightened itself, and the breathing at once became easy. Examination of the escaped fluid showed the presence of hooklets, and the only further question was the extirpation of the echinococcus. He determined upon incision and drainage. He accordingly incised and inserted a drain on September 2d, and in the beginning of December, as no more cysts by that time appeared, the drainage tube was removed, and in a day or two the wound healed, and at the date of the report the neck appeared quite normal.—*Medical Press*, November 5, 1884.

ANTISEPTIC TREATMENT OF PULMONARY DISEASE BY MEANS OF PNEUMATIC DIFFERENTIATION.

By HERBERT F. WILLIAMS, M.D.,

ASSOCIATE SURGEON ST. MARY'S GENERAL HOSPITAL, BROOKLYN, N. Y.; CONSULTING PHYSICIAN TO BUSHWICK AND EAST BROOKLYN DISPENSARY.

In the spring of 1876 the author read a paper "On the Treatment of Chronic Pulmonary Affections" before the Medical Society of the County of Kings, which closed with these words: "I hope the time will come when the cure of lung affections can be traced to the topical application of appropriate remedial agents."

It is my present purpose to present to the profession the result of my labors in this direction for the last nineteen months. The term "topical application" is replaced by that of my title, antiseptic treatment of pulmonary disease by means of pneumatic differentiation.

While pursuing the study of the effect of altitude upon the lungs, and diseased lungs in particular, I called to my assistance the ripe scientific knowledge of my friend, Mr. Joseph Ketchum, of this city, to whom we are indebted for the mechanical invention known as the pneumatic differentiator or pneumatic cabinet, and in its application I am pleased to acknowledge his able assistance in many important particulars. I further acknowledge the able assistance of Drs. W. A. De Watteville, of New York, and Sidney A. Fox, of this city, who have been energetic colaborers in many of the results thus far attained.

It would be wearisome to recite the terrible statistics of the ravages of the different forms of pulmonary consumption, indeed, it would not be just to the subject, for I am not ready to assert that the statistics in cases of advanced degeneration can be materially changed.

In these investigations I claim the indulgence due a pioneer, for, however fortunate my efforts may have been, subsequent study of the forces I shall presently describe will show wider application and certainly better results.

Pneumatic differentiation may be thus described: It consists in immersing a patient in a partial vacuum, thereby removing to a sufficient degree the external pressure of the atmosphere, and at the same time supplying the lungs with air at its normal pressure, and to a greater or less extent impregnated with the substance which it is desired to administer.

The degree of rarefaction to which it is desired to subject the patient is usually that represented by the fall of from one-tenth of an inch to two inches of mercury of the barometer. The method preferably employed in rarefying the air in the cabinet is to produce high vacuum in an air-chamber made to communicate with the cabinet, and to allow a sufficient quantity of its air to pass from the latter into the exhausted chamber. The patient is thus relieved from the successive impulses to which he would be subjected by the use of an ordinary air-pump. This is also preferable on account of the celerity and exactness with which the desired rarefaction can be governed. The decrease in the external pressure upon the body, coupled with the normal atmospheric pressure exerted internally, causes an inflation of the lungs and a dilatation of their cells, the extent of which is primarily dependent upon the difference in pressure. The portions of the lungs which may have become inactive and irresponsive to voluntary respiration are thus forced to expand. It is necessary to control the posterior pharynx by a muscular effort, or a suitable clamp must be applied to the nose to prevent the air from escaping through this channel, thereby decreasing rarefaction, and more especially precluding the possibility of forcing the air into the lungs and impinging its contents upon the interpulmonary tissues. Such escape would, moreover, defeat the forcible expiratory effort which is intended to be produced.

This can again be defeated by the patient resisting the external pressure with his mouth, inspiring and expiring through his nose when not clamped, breathing the air of the cabinet. When properly conducted, a calisthenic action is produced, in itself beneficial.

The great advantage is the fact that under given conditions of temperature, air at normal density affords its best vapor-carrying capacity. Antiseptic air thus administered must condense at the instant of increased pressure due to the active expiratory effort. Thus it will be seen that air charged to its utmost limit with remedial agents can be made to deposit its contents in cavities or other diseased portions of the lungs. The removal of the external pressure has, moreover, the beneficial effect of causing a corresponding expansion of air which may be imprisoned behind obstructions in the bronchi, thus serving to forcibly expel such substances. When there are evidences of lung collapse from infarctions, it is well to request the patient to take as full an inspiration as possible before the air about him is rarefied, maintaining himself in this act until sufficient vacuum is produced. The larger quantity of air thus imprisoned becomes expanded, and may facilitate the expulsion of the offending foreign matter. This same expansion takes place in the eustachian canals, and necessitates the advice to frequently swallow, while the air is being removed, thus equalizing the air-pressure and relieving the tympani. When breathing the external air, should the patient become fatigued, communication with the external air can be cut off and he can respire the air of the cabinet until treatment is resumed.

The study of the influence of this process upon the circulation is very interesting, but will occupy too much space at this writing. Both in theory and practice it is found that when respiration is once established in the differentiator at a pressure say of 6 to 10, the effects on the healthy lung, proven as they are by well-known physiological data, and on a series of careful experiments made in conjunction with Drs. De Watteville and Tiegel, show that when respiration is conducted slowly the increased air-pressure from without puts the thorax into a condition known as forced inspiration. This inspiration differs from the ordinary one by being nearly passive. It is followed by an exceedingly active expiration which brings the thorax nearly into the condition of ordinary expiration. The active and passive movements of the respiratory act thus becoming reversed, the breathing takes place not only with the ordinary respiratory air, but with the complemental air.

We know that during ordinary inspiration the blood-pressure rises in the arterial system of the body because the blood finds less resistance in its passage through the lungs, and that during expiration the blood-pressure sinks accordingly.

This inspiratory effect is very much increased by the differentiator, and in such a manner that the difference in

blood-pressure in inspiration and expiration is also increased and the main arterial pressure of the body becomes inevitably greater, consequently we have, while breathing in the cabinet, a lowering of the capillary blood-pressure of the lungs which is sufficient to stop or diminish serious pulmonary hæmorrhages, as clinical experience gained up to this time amply shows.

The proofs of these statements and detailed description of the experiments pursued in conjunction with Drs. De Watteville and Tiegel will be made the subject of a special essay by the latter.

The following table will show the number and character of cases and the result in each case to date.

The lower table shows approximate barometric equivalents.

	Total cases.	Recoveries.	Improvements.	Non-improvements.	Deaths.
Nervous cough	2	..	..	2	
Bronchitis	20	20			
Unresolved pneumonia	3	3			
Primary infiltration	7	6	1		
Acute catarrhal phthisis	9	4	1	2	2

Abscess of lung	1	1			
Atrophy of lung	1	..	..	..	1
Total	62	34	10	7	11

Approximate Equivalents of Fall of Barometric Column in Tenths of Inches.

Fall of barometer	.1	.2	.3	.4	.5	.6	.7	.8	.9	1.
Equivalent in parts of an atmosphere	1-300	1-150	1-100	1-75	1-60	1-50	7-300	2-75	3-100	1-30
Equivalent in pressure per square inch	.05	.1	.15	.2	.25	.3	.35	.4	.45	.5
Equivalent in altitude in feet.	100	200	300	400	500	600	700	800	900	1000
Equivalent in inflating pressure (lbs.)[1].	10	20	30	40	50	60	70	80	90	100
Equivalent in energy developed in expiration (lbs.)	10	20	30	40	50	60	70	80	90	100

The rarefaction used varied from one-tenth of an inch to one inch fall of the barometric column.

The time occupied in treatment ranged from ten to thirty minutes.

In the majority of cases daily applications were made. The greatest number of applications given a single case was one hundred and five. This was a case of recovery from acute catarrhal phthisis, and will be fully detailed further on.

The smallest number of applications was two each to three cases of acute bronchitis, all of which recovered.

The cases reported in the death column were all advanced. Two were greatly benefited. The first was a case of chronic tuberculosis of three years' standing, unable to lie down in bed for nine months previous, to comb her hair, to go up or down stairs unassisted. Her only open-air exercise for three months previous to treatment, September 20, 1883, was in an invalid's chair, and in this manner it was necessary to convey her to my office, one-fourth mile in distance. At this time her morning temperature was subnormal; in the afternoon it averaged 103° F. Extensive degeneration had taken place in anterior portion of left lung; the inferior lobe of the right lung was bound down by pleuritic attachment. This so compromised her breathing capacity that the slightest exertion was intolerable. She was placed in position in the cabinet, and with frequent interruptions breathed against one-tenth inch fall of the barometer for seven minutes, inhaling a one to one thousand solution mercuric bichloride and one to one hundred carbolic acid solution, mixed. Her respirations before beginning treatment were thirty-eight per minute; while breathing in the cabinet they were eighteen.

September 21st.—The difference in pressure was increased to two-tenths, breathing nine minutes. Treatment was thus conducted, gaining each day both in difference of pressure and time, until six-tenth inch and thirty minutes were attained respectively. She soon became able to lie down in bed, to walk about her house with ease, sleeping and eating well, expectorating freely and easily. In due season her invalid's chair was abandoned, and October 29th she rode a distance of a mile and a half in the horse-cars and did some light shopping. She was now walking to and fro to my office.

November 4th, she attended church.

November 10th, after forty-three applications, her respirations outside the cabinet were eighteen, and inside eleven. Her morning and evening temperature was normal. At this date, by advice of her physician, Dr. William Swift, who kindly corroborates these statements, she sailed for Florida, where she remained until May of this year with continued comfort. On her returning voyage she suffered from sea-sickness to such an extent that the captain of the steamer expressed great relief on safely landing her. She was found to be suffering with thrombi, one of which had lodged in her right subclavian or brachial artery. She never regained the full pulsation or warmth of her right arm. She suffered from frequent attacks of dyspnœa for the two weeks following, when she died.

The other case, tubercular phthisis of over two months' standing, with degeneration of apex of left lung and infiltration of right. This case gained ten pounds in weight, which was maintained for three months. Her general condition improved to such an extent that a permanent recovery seemed probable. The patient, failing to report for two weeks, was visited at her home, where she was found to be suffering with acute intercurrent inflammation, due to exposure in returning from an evening's entertainment. After a time treatment was resumed, but no improvement followed. Patient becoming discouraged after fifty applications, treatment was abandoned. Patient died three months after. The other cases, with one exception, were relieved, though no conclusion could be reached with reference to prolongation of life.

The histories of five cases of phthisis that recovered are as follows:

Case 1.—Miss S——, aged twenty-two, weight one hundred and six pounds; mother and paternal grandfather died of consumption. Patient contracted cold in February, eight months previous. She was first seen March 5, 1883, when evidence of consolidation was obtained. From this date she continued under the treatment usually adopted in like cases. In July she was sent to the mountains, where for the first four weeks she improved, but, to use her own words, for the last two weeks it was her daily prayer "to live until she could reach home." She returned August 1st, when her symptoms became greatly aggravated—hectic, temperature reaching 104° daily, excessive night-sweating, constant cough, unable to eat or sleep, expectorating less than in the mountains, losing flesh and strength rapidly, menses absent for two months. A cabinet involving the principles of the differentiator was rapidly constructed and treatment commenced September 5, 1883. Physical examination in conjunction with Dr. George R. Fowler.

Inspection.—Shows depression in supra- and infra-clavicular spaces, most marked on right side, respiratory movements of right side somewhat restricted, respiration thirty-two per minute.

Percussion.—Right side, anteriorly: Dulness in superior portion, very high-pitched note in second intercostal space one and one-half inch from sternum. Left side: No marked deviation from health.

[1] This is calculated on superficial area presented by a ten inch square front and rear.

Auscultation.—Right side, anteriorly: Marked respiratory murmur, accompanied with large rhoncus, which begins at about one-half of expiratory act and continues to end; cogwheel respiration throughout the frontal aspect, with exception of region of sternum clavicular angle where the respiratory sounds are feeble. Left side: Cogwheel respiration and prolonged expiratory murmur, rather bronchial in character, numerous bronchial râles.

Diagnosis.—Acute catarrhal phthisis, stage of softening. At this time, and for several days previous, she refused medicinal treatment, and could only be induced to take eight grains of quinine daily, which was continued for a short time, when all treatment but the daily resort to the cabinet and the medicine thus administered was abandoned. At the first treatment one-tenth inch pressure for ten minutes was maintained, inhaling a one to one-thousandth mercuric bichloride solution. September 6, 1883, at the second treatment, two-tenths pressure was reached, which the patient controlled perfectly. On her way home, accompanied by her mother, she was seized with a paroxysm of coughing, and ejected upon the sidewalk what her mother described as a piece of maccaroni; this was probably a bronchial cast; easy expectoration followed, and after reaching home the amount expectorated during the day, as estimated by her mother, was a pint.

Daily increase in pressure was made, and from twenty to thirty minutes was spent in the cabinet. The expectoration and cough gradually diminished, the fever subsided, and on September 25th menses returned.

December 18, 1883, was re-examined in conjunction with Dr. George R. Fowler, and it is agreed that there is an entire absence of the previous condition. The only abnormality remaining is a slightly high-pitched percussion note in the right lung.

Patient now came once a week, gaining in every particular and continuing until this spring, taking in all one hundred and five applications.

Iodine was sometimes substituted for the bichloride solution and at others the combination was used.

She took one bottle of Gardner's syrup of the hypophosphites after treatment had commenced. On two or three occasions she has caught severe colds. At such times she hastens to the cabinet and in one or two applications relief is afforded. She is now in perfect health, weighing one hundred and twenty six pounds, the life of the household, and an expectant bride.

Case II.—Mr. W——, aged twenty; weight one hundred and eight pounds; unmarried; machinist; no hereditary history of phthisis; physical examination made in conjunction with Dr. Charles Jewett.

History.—The patient has been suffering for eight weeks with hacking cough, high fever, pain in right side, raising very little for first month. One week since had a copious expectoration, appetite better since; excessive night-sweats.

Inspection.—General signs of emaciation. Slight flattening in right sub clavicular space.

Palpation.—Fremitus increased right side anteriorly and posteriorly.

Percussion.—Right side anteriorly: Gentle percussion reveals high pitched note from supra-clavicular space to fourth intercostal; forcible percussion shows tympanitic quality in sub-clavicular region. Posteriorly there is dulness. Left lung shows slight extra resonance anteriorly.

Auscultation.—Right lung shows marked amphoric respiration in superior mammary region, greatest intensity about fourth intercostal space, forcible expiratory effort producing gurgles in great profusion.

Diagnosis.—Consolidation of upper lobe of right lung, with large cavity in centre of consolidation.

This patient, like the others, was subjected to gently increased pressure, using principally the mercuric bichloride mixed either with carbolic acid or iodine. Eighty treatments in all were given. General symptoms gradually improved, weight increased to one hundred and sixteen pounds. Re-examination in conjunction with Dr. Jewett disclosed absence of moisture and activity in the cavity described. Patient resumed occupation as machinist in Brooklyn Navy Yard last March, where he is still employed.

Case III.—Mr. M——, aged twenty-six; clerk; married; weight one hundred and eleven and a half pounds; family history negative. Used to outside life till two years ago; occupation keeps him sitting. Slight cough commenced a year ago; first hemorrhage two weeks since. Has lost thirty pounds in last year. Gradually increasing weakness.

Inspection.—General appearance anæmic. Depression in clavicular regions, right side. Respiration, 24.

Palpation.—Vocal fremitus increased right side superiorly.

Percussion.—Right side, anteriorly: Dull percussion note in clavicular regions, extending to third intercostal space. Other portions normal.

Auscultation.—Right lung anteriorly: Prolonged expiratory murmur, wavy in character; expiratory sounds lacking in vesicular element; sibilant and sonorous râles are detected. Left lung: The respiratory murmur is somewhat exaggerated.

Diagnosis.—Primary infiltration at apex of right lung.

Treatment commenced October 31, 1883. Thirty applications given, when the infiltration cleared up, and all the other symptoms disappeared.

Patient remained well till July, 1884, when, sitting in Central Park, he was seized with hæmoptysis. Treatment was immediately resumed and continued for some time. He is unafflicted at present. Now weighs one hundred and sixteen pounds.

Case IV.—Mr. M——, aged twenty. The history and progress of this case show that eighteen months previous to my examination (November 23, 1883), he was sick with what his attendant called pneumonia. Surviving the acuteness of the attack, his condition was critical for several weeks. After a time profuse expectoration took place and slight improvement followed, nature doing her best, with little assistance from art. Patient has been raising half a pint daily for several months, coughing so violently that food is vomited.

Inspection.—Shows general emaciation, swelling of right leg and ankle.

Palpation.—Right side, vocal fremitus normal; left, anteriorly weak, posteriorly absent.

Percussion.—Right side normal, except high-pitched note in mammary region; left, absolute dulness, with exception of slight vesicular resonance in sub-clavicular and supra-scapular regions.

Auscultation.—Right side: Puerile respiration posteriorly and anteriorly, with the exception of inner mammary region, which presents the following—the heart is tilted over so that the intensity of its apex-beat is at a point one half-inch below right nipple; apex-beat is diffused, but the general displacement is from five to six inches. The left lung shows a vesicular element in the sub-clavicular space; the respiration becomes bronchial in the mammary and upper axillary and superior scapular regions; there are no respiratory sounds below these points.

Diagnosis.—Necrosis of left lung, caused by pressure of pleuritic fluid; enormous thickening of left pleura with complete obliteration of lower pleural cavity of this side; large pus-cavity connecting with bronchus and displacing heart.

The day following examination I inserted the aspiratory needle over the point of greatest dulness, puncturing the chest to the depth of four inches. High vacuum was connected with the needle, but no pus followed. After some deliberation, on account of the malposition of the heart, it was decided to try the influence of the differential air-pressure, and on December 3, 1883, the first trial was made. He respired against two-tenths of an inch fall of the barometer for eight minutes, inhaling a one to one-thousandth solution mercuric bichloride.

With few exceptions, daily applications were made, and, at the fourteenth, seven-tenths pressure was reached. The patient began to show improvement and appetite. Cough was still severe, expectoration increased. From the twenty-ninth to the thirty-ninth treatment he complained of pain in the left mammary region while breathing in cabinet. At this time a peculiar sound of air and fluid could be detected in the sub-cellular tissue in the left superior mammary region. This became so marked that in his forty-second treatment air was compressed about him in the cabinet, and he was allowed to breathe into the normal atmosphere, an act analogous to breathing into partial vacuum. This was subsequently repeated by producing rarefaction in the empty cabinet, and requesting him to breathe from the outside into this partial vacuum.[1]

The swelling increased in spite of these endeavors, and became so urgent that a paracentesis was done on the evening of February 29th. A crescentic incision was made in the most dependent portion of the swelling in the third intercostal space, over the normal position of the heart. A large escape of air and about four ounces of pus followed. An antiseptic pad was applied. The wound was treated antiseptically until March 11th, when the treatment in the cabinet was resumed. A wet starched bandage was placed over the fistula, and a three per cent. solution of iodine was used in the spray. When breathing was fully established the characteristic reaction of iodine upon the starch was demonstrated. Pus collected from the fistula eight hours after an inhalation of the mercuric bichloride gave the mercuric reaction on copper plate. This opportunity to practically demonstrate the theories advanced earlier in this paper was as welcome as its result was absolute.[2]

From this time rapid improvement followed. The fistula discharged freely, especially after treatment. The cough diminished, but would recur when there was an impediment to the escape of pus in the fistula. Any obstruction in the fistula was invariably expelled by increased pressure; on one occasion it being necessary to resort to nine-tenths of an inch.

On June 3, 1884, he expectorated his last mouthful of pus and to-day he has a good vesicular murmur front and back, in the superior portion of his lung. The heart has nearly completed its journey back into position but the enormous thickening of the lower pleura, or other changes produced by the eighteen months of inflammatory action in the lower thorax, will forever prevent a normal relation of the parts. A small fistula remains, due to a necrosis of the third rib. His weight to-day is one hundred and thirty-seven and three-fourths pounds.

Case V.—Mr. H——, aged eighteen, hatter, weight one hundred and twenty pounds. A brother died of consumption. Patient has been coughing for two and a half months, has had slight hemorrhage, described as dark red; his phlegm has been frequently streaked with blood. Of late his cough has been constant and harassing. Has been taking hypophosphites and cod-liver oil under his physician's directions.

Inspection.—Slight restricted respiratory movements on right side. Depression in both sub-clavicular spaces.

Palpation.—Fremitus most marked on the right side.

Percussion.—Slightly high-pitched note in both supra-clavicular spaces, highest on right side; slightly high-pitched note on posteriorly right side.

Auscultation.—Respiration in superior portion of right lung branches vesicular; in outer clavicular angle the respiration is bronchial. The respiratory sounds are harsh in the corresponding region of left side.

Diagnosis.—Infiltration of right lung, peribronchitis with ulceration.

Patient began treatment March 8th, using five-tenths inches vacuum from the first. Mercuric biniodide, or bichloride and iodine separately were the agents sprayed. He continued with the hypophosphites, using one bottle after beginning treatment. He was discharged cured on May 1st, weighing one hundred and thirty-six and a half pounds, a gain of sixteen and a half pounds in less than two months, having taken twenty-four applications.

The other cases of primary infiltration which recovered are six in number. Three of these cases gave evidence of breaking down. The progress in each case was unmistakable and in less than two months objective symptoms of their former trouble were removed. Three cases of unresolved pneumonia made rapid and complete recovery, and merit more notice than can be given them in an already prolonged paper. This is also true of the twenty cases of acute bronchitis which recovered. The improved cases are ten in number. It is difficult to classify these, but the majority were cases of fibrous phthisis. One case of this description had been suffering for six years, being compelled to spend every winter in a suitable climate, which he has sought in the principal resorts of this country and Europe. The tri-weekly applications given him last winter were sufficient to occasion a very complimentary comparison by the patient in favor of the differentiator.

Mrs. A——, a case of fibrous phthisis, with bronchiectasis and extensive pleuritic attachment, authorizes the most comprehensive construction of language and predicts even then the failure to adequately express the relief afforded by this process. Mrs. A—— has been supplied with a cabinet at her home, where an ordinary servant successfully manages the apparatus. Improvement in general nutrition, strength, cough, breathing capacity, are the points to which all these cases bear willing testimony.

The unimproved cases are seven in number, and comprise two cases of acute catarrhal phthisis in the third stage, one of fibrous phthisis advanced stage, one of tubercular pleurisy, one of laryngeal phthisis with primary infiltration, and two cases of nervous cough.

It will be noticed that the principal agents used in the spray were the mercuric bichloride and biniodide, iodine, and carbolic acid, used singly or in combination.

To those who cherish the views of Koch, the results in the eleven recovered cases furnish strong confirmation of his theories.

Mr. Ketchum and Dr. F. A. Jewett have made careful microscopic examinations of the sputa before treatment and during its progress.

While the evidence is strongly presumptive that the use of these germicides diminished the quantity of bacilli in several instances, and obliterated them in others, the opportunity for following out this line of inquiry has not furnished sufficient data to permit an unqualified statement.

1. *The question of reduction of fever.*—In most cases a rapid reduction ensued. It can be safely claimed that where fever is due to the absorption of pus in a cavity accessible to the air-current, disinfection can easily be accomplished and the fever will subside. We know that a persistently high fever yields after a time, generally preceded by a copious expectoration. The pathological condition existing in such a case is that of extensive pu-

[1] These expedients have been resorted to in a few cases where emphysema has been present, and for the relief of gaseous distention of stomach and bowels.

[2] There is no doubt that agents thus administered are carried to the ultimate alveoli. Cinchonism has been produced by inhaling quinine; mydriasis by inhaling a solution of atropia. In using the mercuric solutions we found it necessary to restrict their use, in one case after three treatments specific symptoms appeared. An experiment upon a full-grown rabbit was made as follows: Tracheotomy was done without the use of an anæsthetic. A canula of one-tenth inch inside diameter was introduced and tied; to this a rubber tube one-fifth inch in diameter and eight inches in length, was made to connect with the outside of the cabinet. An assistant held the rabbit in position, and a mixture of China ink and water was sprayed into the tube. The point at which the animal's ability to expire against the normal atmosphere was reached at seven-tenths of an inch; artificial expiration was resorted to, and the rarefaction was increased to nine-tenths of an inch. This was maintained for ten minutes. The spray was shut off, tube disengaged, and the rabbit allowed to run about the floor for ten minutes, which it did with no apparent discomfort. Its spinal cord was now ruptured and the lungs immediately removed. Microscopic examination shows pigmentation more marked at base of lungs, yet deep discoloration is seen at different points in the sub-pleural spaces on the periphery. Microscopic observation of fresh sections cut transversely from without inward from all parts of the lungs, shows abundant pigmentation in the ultimate alveoli. China ink was selected because of its utter insolubility, fineness of its particles, and the length of time which it will remain in suspension.

trefaction in the parenchyma of the lung, unconnected with a bronchus, ulceration and breaking down continuing until a bronchus of sufficient size is reached, when excavation is possible. To introduce antiseptic or germicidal air into freshly made cavities will as certainly reduce temperature as will washing the uterus in puerperal septicæmia. It is true that phthisical patients may have fever dependent upon conditions outside of the lungs; such cases have been met, and beyond the fact of facilitating oxygenation of the blood and increasing its interchange in the tissues, this process did not exert any influence. Where the lesion is primarily pleuritic, while I believe that a gentle force will exert a salutary influence, over-zeal might enhance the danger of increasing the quantity of plastic exudate, when of course the fever would not subside. In febrile cases morning treatment is preferable, for analogy, if nothing else, tells us that quiet and repose are the best febrifuges for these conditions.

2. *The influence upon the cough.*—Experiments have been made upon the same individuals while breathing a strong aqueous solution spray of iodine in and out of the cabinet. While it is extremely rare that one can inhale this solution outside without coughing, it is still more rare to find one who cannot while breathing with a medium pressure in the cabinet. The probable explanation of this is that owing to the stretching of the walls of the larynx and the pharynx the terminal nerves are rendered less sensitive. This is analogous to pinching the integument to relieve the pain of hypodermic procedure.

The effect upon the permanent cough depends upon the lesion. Great ease of expectoration and tendency to sleep after treatment have been noted in most of the cases, the permanent and temporary relief from cough also depends largely upon the selection of medicinal agents, those used thus far having been so limited, the intention being to produce antisepsis. The more emollient remedies have been ignored. The range of possibilities in this direction is so great that future experience will establish the comparative value of agents, not only for the relief of this symptom, but for the cure of the lesion upon which it depends.

Dr. A. S. Houghton, a former assistant, now located in Milwaukee, Wis., has been supplied with a cabinet with which he is getting good results with a different class of remedies. He reports favorable results in five cases of phthisis in which he used a spray of the hypophosphites, also administering these agents internally, selecting a trituration of the dry salt. By the combined use of these agents he claims a speedy arrest of destructive progress by promoting calcification.

3. *Effect upon expansion and respiration.*—The increase in the former in the recovered and improved cases was from twenty-five to one hundred and fifty per cent., and the number of respirations per minute was reduced accordingly. Spirometric tests show an increase in volumetric capacity of from twenty-five to one hundred per cent.

4. *Effect on hemorrhage.*—This properly comes under the head of circulation, and, as before stated, will be discussed in a special paper by Dr. Tiegel. Of the thirty-two cases of phthisis reported, nineteen have suffered from hemorrhage at some time during the course of their disease. Of these three had slight hemorrhage while under observation. One case was submitted to treatment during the attack, and the hemorrhage was checked. Another patient had suffered from repeated attacks within a space of six weeks before taking the treatment. Nineteen applications were made with a maximum pressure of five-tenths of an inch. No hemorrhage occurred while breathing in the cabinet and only one while under treatment, and that after a violent paroxysm of coughing at his home; treatment was continued the following day. The third case had primary infiltration and reported a hemorrhage during the previous evening; treatment was continued daily until recovery. It would seem, therefore, that in this process we have a force not only not calculated to produce pulmonary hemorrhage, but to arrest or prevent it. This does not refer to accidental conditions nor to denuded arteries that may lie athwart cavities or to aneurismal dilatation of pulmonary vessels. Realizing this fact, a constant vigilance has been kept for fatty hearts and atheromatous arteries, for here, if anywhere, hemorrhagic mischief may arise.

5. *Effect on menses.*—In all seventeen cases of phthisical women were treated, two of whom had reached the menopause; of eight in which menstruation had ceased, in four it returned; of seven in which it was scant, six became normal. This is a further proof of the increase of the main arterial pressure produced by this process, these organs responding to the general arterial plethora.

6. It has been urged that where this process is brought to bear upon the attenuated and toneless walls of the bronchioles and alveolar septa, conditions dependent upon the prodromata of phthisis, dilatation and rupture might be produced. It is probably true that even in a healthy condition a reckless resort to the force at our command would produce even worse mischief.

It will be remembered that the limit thus far advised is two inches fall of the barometer, and in the majority of the cases reported one inch has not been reached.

Analyzing an ordinary forcible cough we find that a full inspiration is first necessary. The glottis is now closed, and compression of the lungs and their contents is accomplished by the respiratory muscles. The glottis is then opened and the compressed air escapes with more or less explosive force.

To measure this force it will be necessary to cough against a properly arranged mercurial column, when a displacement of from four to eight inches will be shown. This being a static force must be exerted in all directions and is largely in excess of any thus far advised in this process.

It would seem, then, that higher vacuum could be used with impunity so far as this danger is concerned. I have found cases where the full limit could not be reached on account of overstretching pleural or diaphragmatic adhesions, causing a sharp pleurodynia. When such pain has occurred I have immediately strapped the side down with adhesive plaster, and the trouble has quickly subsided.

The reader who has done me the honor to follow thus far will appreciate the difficulty I have experienced in presenting full data seriatim in each case. Long and intricate tabulated statements are dry reading and seldom engage attention. Work in unexplored fields is necessarily imperfect at first; new suggestions present themselves dependent upon peculiarities in individual cases.

The effect of posture during treatment, of antagonizing the respiratory muscles of the healthy lung, thereby forcing the corresponding muscles of the diseased one to increased effort, the application of chemically dry air, and the study of the personal equation, are questions of interesting inquiry at present, but it takes time to draw rational conclusions.

Thoughtful physicians know that everything depends upon the early recognition of a phthisical departure from health, that the stage of inflammatory infiltration, though considered the primary stage, occasions knitted brows and anxious hearts when those we love are thus afflicted. There must be a time when the treatment I have described is most applicable. There are cases, or perhaps periods in the progress of all cases, when it is inapplicable. From the facts already demonstrated it is safe to conclude that the earlier the full provisions of this treatment are carried out, not only are the chances of recovery better, but the opportunity of meddlesome interference is prevented. It is not intended to supersede the benefit of climate, for arrangements can be made by which these cabinets can be placed in any desirable locality. It certainly cannot interfere with any of the

medicinal and nutritive measures known to be of inestimable value. To all these it is a valuable adjunct, and at times it will assume the position of principal when those who will have observed its power will remember my closing words with forbearance:

Phthisis has been cured by the topical application of appropriate remedial agents.

131 Gates Avenue, Brooklyn,
December 17, 1884.

A CASE OF DIFFUSE ROUND CELLS ARCOMA,

Involving the Posterior Nares, Vault of the Pharynx, Soft Palate, Pillar of the Fauces, Right Tonsil, and Lower Pharynx; Operation; Cure.

By F. H. BOSWORTH, M.D.,

Professor of Diseases of the Throat in the Bellevue Hospital Medical College, New York.

The following case is presented as affording many points of great interest on account of its exceeding gravity, the extent to which the malignant growth had invaded the tissues of the fauces, the somewhat novel method by which it was extirpated, and the complete success attending the operation.

J. T. H——, aged forty-two, a gentleman prominent in public life in one of our Western States, consulted me on June 26, 1882, at the request of Dr. Henry Evans, of Sedalia, Mo., giving the following history: When a child he fell, receiving a blow upon the nose which resulted in a deflection of the septum by which the right nares became almost completely occluded. This caused but little annoyance in early life. But for several years he had been much troubled with an ordinary nasal catarrh. During the spring of 1882 he was under treatment for this, but with no marked relief. About February 15, 1882, his physician discovered a tumor in the vault of the pharynx which he regarded as a glandular hypertrophy. Mr. H——, however, had been conscious of a fulness in this region for some months previously, and had at the same time been conscious of an increasing faucial secretion. Local treatment was applied to this for about two months, until April 13th, when a portion was removed with the forceps, which upon examination was pronounced benign in character.

Mr. H—— went to Missouri about May 1st, remaining six weeks. While in Sedalia, early in June, Dr. Evans saw him, and after a careful examination of the growth pronounced it malignant, and advised him to come immediately to New York. I might mention in this connection, that on his way to New York he saw Dr. William Porter, of St. Louis, and Dr. Cohen, of Philadelphia, who regarded the growth as malignant and gave an unfavorable prognosis.

By this time the discharge from the tumor had become exceedingly fetid and offensive, and considerable in amount. His general health also had become markedly impaired.

On June 26th he came to my office. At this time he was in an exceedingly enfeebled condition, the walk to my house, and the climbing my steps causing him considerable effort. He was noticeably emaciated, the skin of a sallow, unhealthy color, the pulse 120, and temperature 101°. On examination of the fauces there was noticed a brownish, unhealthy-looking discharge from the pharyngeal vault, which gave forth an exceedingly unhealthy odor. The soft palate was of a dark-red, mottled appearance, especially on the right half, and seemed to be crowded forward by a growth behind it. By palpation a hard, dense mass was felt, of a rounded and slightly irregular outline, which seemed to fill the pharyngeal cavity and extend down to the edge of the soft palate. On lifting the velum with a probe the lower edge of the mass was brought into view, of a pale pinkish color and pultaceous aspect. The palato-pharyngeal space was completely blocked up. Protruding between the growth and the palate were a number of blackened shreds of necrosed tissue.

The whole aspect of the case was most discouraging, as I felt convinced that the tumor was malignant. Furthermore, any question of a radical operation was not to be thought of, Mr. H——'s general condition being such that I had little hope of his surviving such a procedure. The plan of treatment that I decided upon was to remove the tumor piecemeal, taking off small masses at a time and in such a manner that all shock to the system should be as far as possible avoided. This was accomplished by means of the wire snare ecraseur, the instrument I used being the curved modification of Jarvis' snare, as adapted by myself for operations on adenoid growths in the vault of the pharynx, and described in a paper published in the New York Medical Record, January 13, 1883. The snare being mounted with a No. 5 piano wire, a small loop was arranged and pressed upon a small portion of the border of the growth, and the screw being turned, the loop would bury itself in the soft tissue, and in this manner a portion perhaps not larger than a split pea would be taken off.

In this manner several small pieces were removed the first day I saw the patient. Immediately on cutting off a piece of the tumor, the parts were showered with a weak solution of borax and carbolic acid until all pain and irritation were allayed. In this manner I operated every day, removing small portions successively until my patient was too much wearied to proceed.

A piece of the growth was sent to Dr. William Welch, who reported on June 30th: "The specimen consists of a number of fragments, the largest the size of a small bean. Their consistency is rather soft. After hardening with alcohol, sections were prepared and examined microscopically. The surface of the specimen is covered with laminated flat epithelium. Beneath this the new growth begins at once. This new tissue is composed of lymphoid cells chiefly, between which is a reticulum of anastomosing fibres. In addition there are some fusiform and branching cells, and here and there giant cells, the nuclei of which are mostly in the centre of the cell. The structure is therefore like that found in lymphatic glands, and called lymphatic or adenoid tissue. There is no alveolar arrangement to be observed. The growth is therefore a sarcoma. The main features are those of lymphosarcoma, but the type is somewhat mixed by the presence of the giant cells."

From June 26th to July 12th I saw him daily and operated as above, removing a number of pieces. His condition at this time became somewhat alarming. His strength was failing and he was suffering much from neuralgia of the face. I therefore sent him to the sea-shore near the city, where I could continue my daily attendance. A few days at the sea-shore seemed to revive him greatly.

By July 16th I had removed a considerable extent of the lower portion of the growth, and now came upon a large necrotic mass embedded in the growth, which I was enabled to remove. This was about the size of a walnut and seemed to be a superficial slough, the result of pressure exerted on the surface of the tumor, the different lobes, as it were, growing from the sides of the pharynx and crowding upon each other. With the removal of the slough, the neuralgic pain was relieved, the fetid discharge and offensive odor disappeared, and in every way his general health improved. He had evidently been suffering all this time with a mild septicæmia, the result of absorption from this necrotic mass.

July 23d.—The parts from which the growth had been extirpated were cauterized with the galvano-cautery, resulting in some inflammatory reaction, which compelled me to desist from operating.

July 30th.—The growth so far cleared away that its extent can be seen involving the whole of the upper pharynx and its lateral walls, surrounding the Eustachian orifices of each side, and forming a fringe, as it were, about each

posterior nares, but not extending into the nasal cavities. There was also found to be a long fusiform mass extending along the upper surface of the soft palate from the right side of the uvula to the junction with the hard palate. His general condition was now everything that could be desired, and rapid progress was made in removing the growth. I might add here that the loop was placed in position in the pharyngeal vault by means of the rhinoscopic mirror, Mr. H—— holding the spatula in one hand and drawing forward his palate by a palate-hook with the other. Galvano-cautery used over the surface operated upon, followed by inflammatory reaction, not very well marked, however.

August 4th.—Galvano-cautery used.

August 8th.—Returned to the city; doing well.

August 15th.—Galvano-cautery; considerable reaction.

August 27th.—Galvano-cautery used; reaction very marked, so much so that the operation had to be given up for several days.

At this time I sent a specimen of the growth removed from the vault of the pharynx to Dr. Charles Heitzman for examination. His report was as follows: "Numerous medullary corpuscles, greatly varying in size and shape, some nucleated, others coarsely, others, again, finely granular, are closely pasted together, and separated from each other by scanty cement-substance, or fibrous basis-substance. The blood-vessels traversing the tissue are very scanty. Diagnosis: round-cell sarcoma, or globo-myeloma of a very malignant type. Tumors of this kind, after extirpation, almost invariably recur, and within a few months or years cause a fatal termination."

September 9th.—Galvano-cautery used, and following this there was a very marked aggravation of all the symptoms; the growth on the soft palate assumed an angry and threatening aspect.

September 12th.—The growth on the soft palate extended through the palate and down on the right tonsil and anterior pillar of the fauces. I now removed a number of pieces from the soft palate and tonsil.

September 20th.—There appeared a new centre of development on the lower pharynx, and on September 25th it had so far extended that it now involved the right half of the pharynx down to the level of the epiglottis, the right tonsil, the right anterior pillar of the fauces and a portion of the soft palate, part of the palate having been removed. There was also a considerable portion of the growth remaining in the pharyngeal vault. The whole aspect of the case was most discouraging.

Dr. Frank H. Hamilton and Dr. Beverley Robinson now saw the patient with me in consultation, and both expressed the opinion which I entertained, that the case was hopeless.

I felt convinced, however, by this time, that the galvano-cautery was responsible in no small degree for the bad turn which the case had taken, and determined to follow out my original plan of procedure, but without the cautery. At each application of the cautery a notable inflammatory reaction had set in, and this had been more marked with each successive application, and finally there were grounds for thinking that the reaction and rapid extension of the tumor were in no small degree due to its use.

Following the plan, then, of removing the growth piecemeal, while at the same time every possible precaution and care was exercised in avoiding any unnecessary irritation of the parts, I dispensed entirely with all caustics or other applications. As each piece was removed the part was showered with the carbolized alkaline spray till all pain was arrested, and after each operation the cut surface was coated with vaseline. In this manner I very soon commenced to make headway again, and from this time on matters commenced to improve, and with no single untoward symptom developing, I finally completely removed the last portion of the growth, and discharged my patient on November 4, 1882.

The successful termination of the case was unquestionably accomplished by the somewhat unusual method of operating, viz.: by piecemeal; and yet I think that the rare pluck and resolute courage which Mr. H—— displayed throughout these months of weakness and discouragement, contributed in no small measure to the favorable result of what I think must be acknowledged to have been a very remarkable case.

The specimen which I present shows the tumor removed in about two hundred pieces, the whole nearly filling a three-ounce bottle.

Generalizations drawn from the study of a single case do not, as a rule, carry much weight, yet it seems to me that there are several suggestions that may be safely based on this one. The first is, may not a neoplasm, not essentially malignant in its origin, be converted into a malignant growth by attempts at extirpation, which are unnecessarily harsh, and in which too great violence is done to heathy tissues. Mr. Butlin in his recent work on "Sarcoma" teaches, as the result of a careful study of seventy-three cases of malignant disease of the upper air-passages, that sarcoma rarely affects the lymphatic glands, and that it is, therefore, amenable to local measures of treatment. His explanation is that sarcoma "arises by the proliferation of the cellular elements of the solid structures of the connective tissue" which compresses the lymphatics.

In the case above narrated the growth was removed in such a manner that there was the least possible shock to the general system, the least possible violence to the tissue itself, and the healthy tissue beyond the neoplasm was uninjured. Indeed, the healthy tissues were virtually not in the least degree encroached upon. As long as the operation was confined to the removal of small pieces by the snare good progress was made, and there was no appreciable extension of the growth; but as was soon learned by unfortunate experience, when the galvano-cautery was used, while a small portion of the growth was destroyed, such violent inflammatory reaction was excited by the cautery that the growth extended rapidly. My only excuse for using it was that it was the orthodox thing to do. It was finally abandoned, and not a moment too soon, with the result that my patient was rescued from a most desperate strait.

This brings us to another suggestion. Is not the galvano-cautery a much overestimated instrument, and is not quite as much, if not more, harm than good often done by its use? All caustics are an evil, but oftentimes a necessary evil. While they are used to destroy morbid tissue there is always set up an inflammatory reaction in the tissues beyond of a more or less severe character. This is in every case harmful. Any caustic which causes destruction with the least reaction is the best to use. Any caustic which sets up the most severe reaction is the worst. I think I am perfectly justified in the assertion that the potential-cautery, whose action depends on the use of heat, causes a far greater reaction than a chemical agent. In the one case we have caustic action with the addition of heat, while in the use of a chemical agent heat is not present. If, then, we can accomplish what is desired without subjecting the diseased part to the action of this intense heat, it seems to me to be our duty to accomplish our end in a manner which entails the least danger of mischief.

The galvano-cautery is an ingenious and an attractive instrument, and carries an amount of moral weight which, it may be, is not to be neglected, for it certainly impresses a patient with a very exalted idea of the resources at our command, and yet, when we reflect for an instant, it is a very cumbrous, very awkward, and often a most exasperating and treacherous device for accomplishing a small result, viz., to develop a red or white heat in a small piece of platinum, often not larger than a few lines in length.

Early in the galvano-cautery craze I supplied myself with a battery, and subsequently purchased others. I

have not used one now for over eighteen months, for I believe that there is no single indication for caustics which cannot be met in a more efficient, more reliable, more safe, and less mischevious way by other and infinitely simpler methods. Certainly in the case narrated the danger of the potential-cautery was repeatedly shown.

NOTE.—The above case was reported at the meeting of the American Medical Association in May of this year, at Washington, and the patient presented and examined by the members of the Section. His general health was good and the pharynx showed not the slightest trace of any return of the tumor. There were some loss of tissue in the soft palate and right faucial pillar with a few bands of cicatricial tissue, but the absence of cicatricial contraction was noticeable. The parts were soft and elastic, and there was no impairment of function whatever. I last heard from Mr. H—— early in August, and he was then perfectly well.

26 WEST FORTY-SIXTH STREET.

CHRONIC CYSTITIS.

EXTERNAL PERINEAL URETHROTOMY—DRAINAGE—RECOVERY.

BY ALEX. W. STEIN, M.D.,

SURGEON TO CHARITY HOSPITAL (GENITO-URINARY DIVISION), ETC.

CHRONIC cystitis is so often intractable to the ordinary remedial resources of the surgeon, that when the treatment is as signal in its result as it proved to be in the following instance, it is worthy of note. Hence I present an abstract of the history of a patient recently under observation at Charity Hospital.

Daniel R——, aged sixty, Irishman, laborer, admitted August 22, 1884. Had gonorrhœa but once in his life, fourteen years ago, which lasted some weeks. His present bladder trouble began, he thinks, about November, 1883, as manifested by frequent and painful micturition.

September 2d.—Saw patient for the first time; he is extremely feeble, anæmic, emaciated, and expression of face denotes considerable suffering. Says he is obliged to micturate about twenty times during the night, and nearly as often during the day. Nurse says "he is almost constantly in the water-closet." He complains of almost incessant pain in the region of the bladder, and at the glans penis, but the latter pain is excruciating at the close of micturition, when the urine too, is thick and yellowish in color. Search was made for stone with negative result. Flexible bulb, 28 F., largest instrument meatus would admit, was passed to the bladder without obstruction. Finger per rectum found prostate normal, both in size and consistence. Urine high colored, alkaline, slimy, containing ammonio-magnesian phosphates, an abundance of pus-corpuscles, epithelium, a few red corpuscles, and, according to House Surgeon Heller, albumen one-tenth by volume. He was ordered ward tonic, inf. triticum repens, together with potass. citrat.

September 15th.—Bladder to be gently washed out with warm water, once or twice daily.

September 23d.—Injections have been made almost daily until to-day. The bladder tolerates but a very small quantity of water, and the injection creates much pain. Patient complains bitterly of the "washings of his bladder," thinks he is worse since they were commenced and begs that we would desist.

September 24th.—All search for the cause of the cystitis, hitherto made, having proved negative, and the patient evidently requiring immediate relief, an exploratory perineal incision was decided upon. Patient was etherized. Staff introduced into urethra. An incision about one and a half inches in length was made on the raphe of the perineum, about one inch anterior to anus, the membranous portion of the urethra was laid open sufficiently to freely admit the index-finger. Digital exploration reveals what appears to be simply a prominent ruga on posterior wall of bladder, the remainder of the mucous surface being covered with a slimy, stringy mucus. A rubber drainage-tube 23 mm. in circumference, smoothly pared off at its open proximal extremity and also perforated at the sides, was introduced just within the vesical neck, while its distal end was connected with a longer rubber tube which reached over the side of the bed into a basin on the floor. A hypodermic of morphia was given, and quinine grs. x., which latter is to be continued night and morning, and partial cinchonism maintained for a few days.

September 25th.—Rested quite well during the night. Pulse, 74. Diet to-day has consisted mainly of milk; some whiskey. Eight ounces of urine collected in basin; some escapes by side of instrument into dressing.

September 26th.—Had good night. Rectal temperature, 99.5°; pulse, 84. Feeling comfortable.

September 27th.—As considerable urine escapes by the side of tube, wetting bed and making patient uncomfortable, the drainage was modified as follows: The distal end of the long india-rubber tube was inserted into a quart bottle, the bottle and tube were filled with carbolized water and attached to the drainage-tube. A siphon-like action was thus established, which aspirated the urine from the bladder as rapidly as it trickled from the ureters, the result being an immediate and a marked increase in the quantity of urine accumulated in the basin, and no escape by the side of the instrument.

September 28th.—Had restless night; complains of pain in region of kidneys; tongue dry and coated; bowels have not moved in several days; drainage excellent; quantity of urine accumulated since yesterday, 38 ounces. P. M.: temperature, 101.4°; pulse, 84. Ordered ol. ricini. Quinine has been continued since operation.

September 29th.—General condition about the same. Quantity of urine last twenty-four hours, 54 ounces. P.M.: temperature, 100.2°; pulse, 88.

October 1st.—No inclination for food; vomits both food and medicine; constant hiccough. Pulse, 100; respiration, 24. (No thermometer on service.) Quantity of urine passed in twenty-four hours, 38 onnces. Nourishment given by enemata to-day.

October 2d.—Extremely feeble; hiccough has continued almost uninterruptedly since yesterday, but stomach is less irritable, and he again takes his milk and whiskey. Pulse, 96, feeble; respiration, 18. Has had slight movement of bowels; 54 ounces of urine has passed, and notwithstanding his otherwise unfavorable condition, the urine has much improved in appearance; there is less sediment and less pus.

October 4th.—Restless night. Pulse, 60, feeble and intermittent; respiration, 14. Hiccough still persists, but much less in frequency; nausea has ceased. Fifty-nine ounces of urine drained in twenty-four hours. Patient pulled out drainage tube during the night; on replacing it this morning about six ounces of urine ran off, indicating great improvement in the retentive power of the bladder. Bowels moved freely in consequence of enema given. (The subsequent notes show, with the exception of a sharp attack of diarrhœa, lasting about thirty hours, the result of indiscretion in diet, a steady improvement in the general condition of the patient.)

October 11.—Pulled tube out of bladder again early this morning, because of the increase of pain in the glans penis, of which he has complained ever since the retention of the tube. Says that the pain always ceases when the tube is removed. On reintroducing tube, five ounces of urine flowed. Meatotomy was performed, and a 21 A. sound passed freely into the bladder.

October 14th—The retentive power of the bladder being so much improved, as is also the condition of the urine, the drainage-tube was removed this evening.

October 15th.—The pain in the glans penis, so con-

stantly complained of since operation, has disappeared. Urine flows both through penis and perineal opening.

October 16th.—Retains urine two and three hours; no pain of any kind; says he has not been as free from pain in a year.

October 19th.—Retains urine sometimes four hours. The quantity of urine passing through penis is steadily on the increase, and the act of micturition is unattended with pain.

October 25th.—Passes water five or six times in twenty-four hours, nearly all through penis.

October 31st.—Wound nearly healed; urine all passes through penis, unless patient strains, when a very small quantity may trickle through minute perineal opening.

January 1, 1885.—Patient is reported as remaining in a much improved and comfortable condition, though it is said he occasionally complains of some pain at the glans penis, and there is still a small quantity of pus discernible in his urine, which is otherwise very pale, almost colorless, acid, specific gravity 1.010, and free from albumen.

In addition to the foregoing history a few points may be noted:

First.—Owing to the extremely feeble and worn-out condition of our patient the operation was undertaken less with the hope of saving his life than with the intention of possibly discovering and removing the cause of his trouble and of mitigating his suffering.

Second.—The drainage was continued twenty days. Let it be noted how effectual was this drainage in keeping bladder empty and the patient dry after the syphon action of the tube was established. It is also remarkable how well the tube was tolerated by the vesical neck; the only pain occasioned thereby was referred to the glans penis; the pain seemed to be constant, though it varied at times in severity, and ceased immediately on the removal of the tube.

Third.—The drainage might have been continued for a longer period, with advantage, perhaps; but the improvement in the condition of the urine and in the retentive power of the bladder was already apparent ten days after the operation. The perineal opening was practically closed in seventeen days after the final removal of the drainage-tube.

Glycerine as an Excipient.—The employment of glycerine in pharmacy is becoming more and more extensive every day, owing in great measure to its property of dissolving various medicinal substances. It is thus very generally used instead of lard or oil in a number of cosmetic preparations. It makes an elegant excipient, but, unfortunately, glycerine will not penetrate the pores of the skin, and prevents also the absorption of any drugs which it may hold in solution. Dr. P. Vigier has recently made some experiments upon himself, which are very simple and may be repeated and verified by anyone, which show in a striking manner the uselessness of employing glycerine as an excipient when absorption of the active ingredient is desired (*Memorabilien*, November 20, 1884). He was never able to detect iodine in the urine after repeated inunctions of a solution of potassium iodide in glycerine (one part to three), but, when the glycerine was replaced by a fatty substance, the presence of iodine in the urine was at once manifest. A five per cent. solution of muriate of morphia in glycerine rubbed into the skin produced not the slightest narcotic effect. A one per cent. solution of sulphate of atropine applied for six hours to the temples caused no dilatation of the pupils. Still more striking was an experiment made with corrosive sublimate. A five per cent. solution of this substance in glycerine was rubbed strongly upon the skin, yet produced not even a reddening of the surface, nor was mercury to be detected in the urine. The result of this experiment leads Dr. Vigier to recommend the employment of a glycerine solution instead of the mercurial ointment as a parasiticide, since with the use of the latter there is always more or less absorption of the drug.

A CASE OF EXTRA-UTERINE PREGNANCY SUCCESSFULLY TREATED WITH GALVANISM.[1]

By D. C. COCKS, A.M., M.D.,

CONSULTING OPHTHALMIC SURGEON TO THE RANDALL'S ISLAND HOSPITALS, AND ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

A remedial agent which can always be depended on to produce a *certain* result in a given class of cases is a desirable addition to our means of treating disease, but when we discover a remedy for a disease or condition which in itself is almost necessarily fatal to life, we can hardly speak too enthusiastically in its praise.

Such a remedy has been given to the profession for the cure of that formerly most dreaded condition, extra-uterine pregnancy, but one now robbed of all its terrors by electricity.

In February, 1883, one of our members, Dr. A. D. Rockwell, read a paper before this Society and subsequently published it in The Medical Record (February 17, 1883), on the successful treatment of extra-uterine pregnancy.

The statements there made were new to me, and made a decided impression on my mind at that time. I had known that electro-puncture had been used in this class of cases, but that electricity applied by the electrodes to the mass, and not into it, would not only stop the progress of the pregnancy, but would destroy the life of the fœtus, and thus allow the fœtal mass to be absorbed, was a revelation to me, as I know it was to many of our members present.

Subsequent reading showed me that Dr. J. G. Allen had used electricity successfully in extra-uterine pregnancy in 1869 and in 1871, and that since that time many other cases had been reported. Nevertheless, it was the reading of the paper by Dr. Rockwell that first drew my attention to this important subject, and if the report of this case serves to keep up the interest which former cases have aroused I shall feel satisfied.

Mrs. H——, twenty-six years of age, had suffered for three years before marriage from ovarian (?) dysmenorrhœa. In December, 1882, I induced premature labor (her first pregnancy) because of placenta prævia. She was last unwell December 13, 1883. In February and March, 1884, she suffered from severe lancinating pain in the left iliac region. On March 10th she had a slight "show," and as these pains continued severe I was sent for.

An examination made March 17th revealed an ovoid, tense growth to the left of and partially in front of the uterus. It was very tender on pressure, and by bimanual examination it was found to be movable independently of the uterus. There was also marked vaginal pulsation on the left side; a subsequent examination showed the same condition still. I then made a diagnosis of extra-uterine pregnancy. On March 27th Dr. T. G. Thomas saw the case in consultation, confirmed the diagnosis, stated that he thought the pregnancy was tubal, that there was imminent danger of rupture, and advised the immediate use of electricity. That same afternoon I applied a strong induced current from a Kidder's battery through the mass. One electrode was placed in the vagina against the growth, the other on the abdomen, thus grasping the tumor between them. The current was passed for about seven minutes, being interrupted every quarter or half minute; at the end of that time a few but rapid interruptions were made. That night the patient suffered some pain, but the electricity was again used on the following day.

March 29th.—The patient stated that she had a "cold sensation" in the left iliac region. The vaginal pulse is less. Electricity again used, and also on the 30th, 31st, and on April 1st, 2d, and 4th. At that time the growth had lost its ovoid form, was less tense, and her breasts were tender. She was seen by Drs. Malcolm McLean and H. T Pierce, who also agreed in the diagnosis.

[1] Read before the Harlem Medical Association, December 11, 1884.

April 9th.—There has been no application of electricity since the 4th inst. The growth has regained its former size; it is more tense. Patient is unwell; breasts are painful and she has slight nausea.

April 15th.—The tumor is growing; it presses the uterus backward and to the right.

April 17th.—Seen again by Dr. Thomas, who states that the uterus is the size of one at the third month of gestation. It is now over four months since the patient last menstruated. He advises the substitution of the galvanic for the faradic battery.

April 19th.—Temperature 101°. With the co-operation of Dr. McCosh I applied a galvanic current (seventeen cells, Kidder, freshly charged); one electrode was placed in the rectum behind the growth, the other in the vagina in front of and pressing on the growth. A constant current was used for a few minutes and was then rapidly interrupted for a like period. The application was very painful.

April 20th.—The *peculiar* pains from which she suffered have diminished in frequency. The sac is less tense.

April 21st.—Twenty cells applied under ether.

April 25th.—No iliac pains for two days. The growth is no smaller, but seems less tense and painful.

April 28th.—We applied thirty cells under ether.

April 29th.—The abdomen was blistered by the electrode used yesterday; there is no pain in the tumor.

May 2d.—The growth is the size of a Politzer's air-bag. The cervix uteri is gaping and pressed back into the hollow of the sacrum.

May 14th.—The tumor *is smaller*. Vaginal pulse *less*.

May 17th.—A flow with all the characteristics of menstruation has appeared.

May 21st.—The flow ceased to-day.

May 25th.—Dr. Thomas examined the patient and found the tumor decreasing.

The patient went to the country and did not return until the latter part of September. She has had neuralgic pains through the abdomen, but different from those felt before. She has menstruated every four or six weeks.

October 1st.—An examination shows the mass to be the size of a small chicken's egg.

December 1st.—Patient still has pain in the left iliac region and pain in defecation; she has passed pieces of membrane (exudation?) from the rectum several times. Careful bimanual examination shows the sac to be still present and to contain "a something," the nature of which I could not make out. I think in six months more all signs of the growth will have disappeared.

This patient suffered for several years with severe dysmenorrhœa. So severe was the pain that at one time the advisability of removal of the ovaries was seriously considered, thus showing that pre-existing uterine disease was associated with, or rather preceded this condition and was the probable cause of it. What relation, if any, can be assigned between the facts of extra-uterine pregnancy and placenta prævia, I leave for you to say and for future observations to determine.

This case clearly shows the superiority of the galvanic to the faradic current. A better opportunity to test their relative merits could not well have been found. It has been fully shown that up to the third month faradism can destroy the fœtus, but in this case, although tried thoroughly, it did not. There is no doubt that the faradic current had a very decided effect, growth was checked, tension diminished, pain lessened; but this effect was only temporary, for on the discontinuance of the treatment evidences of life and growth speedily showed themselves. On the other hand, a moderate galvanic current (of twenty cells) failed to destroy life, and it was not until we used a galvanic current (of thirty cells) sufficient to cause marked contractions of the abdominal and thigh muscles (the patient being profoundly under the influence of ether), both on making and breaking the circuit, that the fœtus was destroyed.

By a rough comparison, then, we may say that a twenty-cell galvanic current is about equal to the full current of a one-cell Kidder faradic battery in the treatment of this condition. The lancinating pains, so peculiar to this condition, ceased at once after this powerful application of electricity. Unlike most of the cases previously reported, the patient has had pains of a neuralgic character in the left side, together with pain in defecation up to the present time (seven months after the last application of electricity).

My object, gentlemen, in bringing this case before you is, first, to impress on your minds the fact that a similar case may present itself to any one of you when most unexpected. One of our members, Dr. Hands, saw in quick succession a case of ruptured uterus and an inverted uterus. These facts should keep us constantly on the alert for these emergencies, and also to be thoroughly prepared for them, so that when confronted by that most merciless of examiners, a case of impending death, we may be able to pass our examination safely, both for ourselves and for our patient. Secondly, to bring out clearly my convictions on the relative values of the faradic and galvanic currents, which, had they been the same and as positive as they are now, would have saved my patient many days of suffering, and myself many days of anxiety, as I believe that, had the galvanic current been used at first, my patient would have been cured, *i.e.*, the fœtus killed in the first or second application.

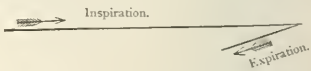
206 East 116th Street.

AN EASY METHOD FOR TEACHING PHYSICAL DIAGNOSIS.

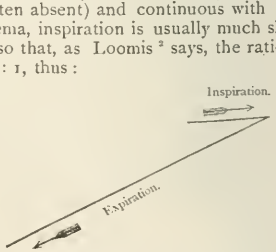
By R. C. M. PAGE, M.D.,

NEW YORK.

After what has been written by Flint, Loomis, Da Costa, and others on the subject of physical diagnosis of the organs of respiration, for me to attempt to say anything in addition appears to be well-nigh superfluous if not presumptuous. And yet there are a few ideas that suggested themselves to me, which, as a student of that subject under Professor Loomis, sixteen years ago, I found to be useful in helping out my fellow-students, and which I propose now to bring forward for the first time. It is the representation of the various kinds of respirations by diagrams. Let us first consider normal respiration. In this case, inspiration (vesicular in quality) is much longer than expiration, which is lower in pitch,[1] and may be represented thus:



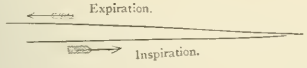
Expiration is merely a short blowing sound when present (it is often absent) and continuous with inspiration. In emphysema, inspiration is usually much shorter than expiration, so that, as Loomis[2] says, the ratio is as 1 : 4 instead of 4 : 1, thus:



According to Flint,[3] the inspiration is less vesicular than normal, raised in pitch, shortened by being *deferred*,

[1] Flint, Respiratory Organs, second edition, 1866, p. 135.
[2] Physical Diagnosis, third edition, 1883, p. 58.
[3] Op. cit., p. 409.

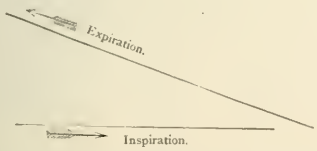
and continuous with expiration, which is lower in pitch. Loomis (op. cit., p. 58) says that the pitch of both sounds is lower than in health. Niemeyer (seventh American from the eighth German edition, vol. i., p. 127) says that at points where there is no catarrh, the respiratory murmur is generally remarkably loud and hissing. Guttman ("Physical Diagnosis," third edition, 1880, p. 109) classes it with *indeterminate* respiratory murmurs. In broncho-vesicular respiration, the inspiration is less vesicular in quality than in health, the pitch is somewhat raised, and, not being quite *finished* (Flint, op. cit., p. 177), is not quite continuous with expiration, which is somewhat higher in pitch, and as long as, or even longer than inspiration, thus:



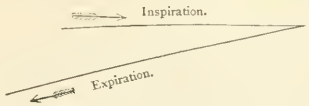
Rude is a short but indefinite (Flint, op. cit., p. 176) term sometimes applied to this variety of respiration. Da Costa ("Medical Diagnosis," fifth edition, 1881, p. 241) terms it *harsh*, and says that "harsh breathing is, in truth, a union of the vesicular and the bronchial sounds." Guttman (op. cit., p. 97) terms *puerile* respiration harsh (rough). Flint (op. cit., p. 409) says the respiratory sound in emphysema, on account of the change in rythm and pitch, and diminution of the vesicular quality, "presents the characters of that abnormal modification distinguished as *roughness*." What, therefore, must be the difficulties in the way of the student, when such distinguished authors apply the same term to such different conditions! The fact is, that harshness (roughness) has nothing to do with the raise in pitch, or the prolongation, or the loudness, of any respiratory sound. Any respiratory sound may possess the character of harshness (roughness), or even be accompanied by râles if the respiratory *mucous membrane* be in proper condition for their production.

Normal respiratory sounds may be harsh (rough), as is often the case in the early stages of acute bronchitis, when the bronchial mucous membrane is tumefied and *roughened* by congestion. They are subsequently obscured by râles. Broncho-vesicular (rude) respiratory sounds are usually harsh, but not necessarily, even in disease. The disease that usually causes this variety of respiratory sound (incipient phthisis) also produces irritation and roughening of the bronchial mucous membrane. On the other hand, in health broncho-vesicular respiration is not infrequently heard at the right apex, and bronchial respiration in the interscapular region (Loomis, op. cit., pp. 34, 35). Both are *smooth* and not harsh or rough. Broncho-vesicular respiration usually depends for its existence upon more or less consolidation of lung tissue; harsh (rough) respiration does not, except secondarily, but upon changes in the bronchial mucous membrane, just as râles do.

In bronchial respiration, the inspiration is still higher in pitch, its quality tubular, and its duration shorter, being unfinished. Expiration is as long or longer, higher in pitch, tubular in quality, and not continuous with inspiration, thus:



In cavernous respiration the pitch of inspiration is usually lower than normal and its quality blowing. In expiration the pitch is still lower and quality blowing, thus:



In the broncho-cavernous variety, the inspiratory sound may be tubular and raised in pitch, and that of expiration low and blowing, or *vice versa*. According to Flint (op. cit., p. 186), "the characters of the bronchial and cavernous respiration may be intermingled in various proportions."

Amphoric respiration (jug-breathing) being frequently only a variety of cavernous respiration, does not need any further mention.

In the same way pulmonary resonance, dulness, and flatness might be indicated by lines giving the ideas of shortness, length and pitch of sound.

Guttman (op. cit., p. 95) says that the characteristic features of the normal vesicular respiratory murmur may be easily reproduced by nearly closing the lips and gently drawing a current of air inwards, etc. The other respiratory sounds, I may add, are readily imitated by arranging the lips as if for *whispering a tune*, and then drawing in and expelling air on the proper key. The diagrams may also be arranged side by side, higher or lower according to the pitch, with normal inspiration as the standard.

Clinical Department.

DISAGREEABLE EXPERIENCES WITH COCAINE.

As was to be expected, the extensive and almost universal "proving," as we believe our homœopathic friends call it, to which cocaine has been subjected, has shown that success does not invariably attend its use, and also, which is of more importance, that it is not without its dangers. We have received a number of communications from correspondents, relating their more or less disagreeable or alarming experiences with this drug.

Dr. Edward S. Peck, of 53 West Fiftieth Street, writes that he has had an experience similar to that related by Dr. Knapp in The Record of December 13th. A young lad with an internal squint of the right eye was operated on without pain after four instillations of a two per cent. solution of Merck's cocaine. Those who were present at the operation noticed an increasing pallor of the face together with a profuse beady perspiration. It was attributed at the time to apprehension, or perhaps to an effort to control pain when the internal rectus tendon was hooked up. There was, however, not the slightest evidence of pain when the tendon was divided. Dr. Peck further calls attention to the error sometimes made of preparing the solution by the addition of hydrochloric acid. It is thus sometimes irritating to the conjunctiva.

Dr. George T. Stevens, of 33 West Thirty-third Street, writes as follows: "I injected one afternoon, beneath the conjunctiva, and along the course of the internal rectus muscle, exactly four minims of a three and one-half per cent. solution of muriate of cocaine. My patient was a man in the prime of life, six feet tall, strong, but very nervous. Six minutes after the injection, Dr. Featherstonhaugh assisting, the operation, which was for the advancement of the internal rectus, was performed quickly and without complication, but not without pain to the patient. The time occupied in the operation could not have exceeded two minutes. In a short time, estimated at about ten minutes, after the operation, vio-

lent convulsions set in attended with desperate struggles to breathe. The face became livid, consciousness was lost, and the patient became uncontrollable. Attempts to administer stimulants were, during some minutes, unsuccessful. After struggling in an easy chair for some time, the patient arose in a state of frenzy and struck violently about, but was at length controlled.

"As soon as possible stimulants were administered, and the most alarming stage of the paroxysm ceased after a duration of nearly twenty minutes. Fully half an hour, however, passed before we could regard our patient as beyond danger. During the violence of the paroxysm, it was impossible to listen to the action of the heart. As nearly as could be determined by examination at the wrist, the pulse was soft, small, and regular, and beating at the rate of eighty per minute. When the patient was sufficiently quiet to allow an examination of the chest, nothing abnormal was observed about the heart. The gaspings for breath were more suggestive of obstruction about the larynx than of the conditions seen in an attack of angina pectoris; but at the close of the paroxysm, the patient was seized with an extreme pain in the left arm, such as often occurs with angina.

"The pupil of the eye, under the conjunctiva of which the cocaine had been injected, became dilated much more than is usual after the use of atropine, the iris appearing only as a narrow line around the greatly dilated pupil. The other pupil was considerably, though not excessively, dilated. I believe that this paroxysm was the manifestation of the toxic influence of the drug. I had, two hours before, administered hypodermically to a young lady three minims of the same solution, and to another lady, not long before, four minims of the same. Neither in these, nor in others in which equal amounts of the identical solution had been used, were any unpleasant results observed.

"An important suggestion occurs in connection with this case, as with those already reported by Dr. Knapp, whether the danger of these injections is not increased in proportion as they are made in close proximity to the large nervous centres."

Dr. Edmund C. River, of Denver, Col., relates the case of a man into whose eyes, preparatory to operation for strabismus, he instilled twelve drops of a four per cent. solution in the course of fifteen minutes—six drops in each eye. After the completion of the operation the patient complained of nausea and a feeling of faintness. The face was extremely pale, hands cold, and skin covered with a cold perspiration. The pulse was 48 to the minute. In a few minutes these symptoms passed off. The following day, in order to determine whether this faintness were due to the action of the drug, twelve minims were again dropped into the eyes in the same manner. No unpleasant effects were experienced. The patient himself said that his distress was due to the knowledge which he had that he "was being cut," although he experienced no pain. He had fainted on a former occasion while witnessing an operation.

Dr. R. McDonald, of Chelsea, Mass., relates an experience with the drug in his own person which was anything but satisfactory. He states that he has been troubled for several years with chronic conjunctivitis, for which he has been in the habit of using sulphate of copper in crystals. The pain resulting from the application usually lasted from fifteen to thirty minutes, never longer. He recently tried cocaine hydrochlorate, dropping two minims of a two per cent. solution in each eye five minutes before touching the conjunctiva with the copper crystal. For fifteen or twenty minutes no pain was felt, but soon after a smarting and lachrymation began and became excessive, and the conjunctiva was greatly inflamed and secreted an abundant thick yellow fluid. Two drops of the cocaine solution were instilled into each eye every twenty minutes, with the effect of temporarily lessening the pain but increasing the inflammation. The theory which Dr. McDonald offers in explanation of this irritant effect is, that a chemical combination took place resulting in the formation of chloride of copper. It may be that in this case the error alluded to by Dr. Peck was committed, of using an excess of hydrochloric acid in making the solution.

UNSUCCESSFUL EMPLOYMENT OF COCAINE.

Dr. James A. Spalding, of Portland, Me., writes concerning an old lady, eighty-eight years of age, who had been blind for eight years from chronic glaucoma. She had lately suffered intense pain in the left eye, for the relief of which iridectomy was proposed. Cocaine was applied five times at intervals of five minutes (the strength of the solution was not stated), and the operation begun immediately after the last instillation. The patient did not feel the speculum or forceps, but began to shrink as the knife entered the sclera, and by the time that an incision large enough for a broad and extensive iridectomy had been completed, she was suffering such agonizing pain that it was found necessary to complete the operation under ether. On the following day five to ten drops of the same solution were instilled into another patient's eye previous to a cataract extraction, and the individual did not feel any of the steps in the operation. "It appears probable, therefore," Dr. Spalding concludes "that in absolute and painful glaucoma cocaine may disappoint us in its local anæsthetic effect. Perhaps a stronger solution may not, even in these cases, leave us in the lurch. Perhaps a more frequent application is necessary to anæsthetize the inflamed region through which the knife has to pass. Perhaps the disease prevents proper absorption of the cocaine by the parts involved."

Dr. C. H. Hughes, of St. Louis, reports that he has met with signal insuccess in two cases of trifacial neuralgia in which he employed freely a two per cent. solution of cocaine hydrochlorate. He was unable to obtain a stronger preparation. But he thinks it improbable that a solution of any strength will suffice to wholly obtund sensibility of the entire affected area in trifacial neuralgia.

DRY CUPPING IN THE TREATMENT OF ANTHRAX.

Dr. E. I. Thorn, of Yellow Springs, O., claims that this method is far superior to the old treatment of carbuncle. He writes: "Upon the appearance of one or more of the small ulcers at the apex of the tumor, apply the cup after inserting a lighted taper moistened in turpentine. In a moment this will open the cells, and there will exude into the cup a teaspoonful, more or less, of sanious pus. Follow this operation with poultices to keep up the discharge, and in a few days the carbuncle will disappear. In this way we avoid from three to six weeks of suffering, and the constitutional results of the usual protracted illness."

EXTRACTION OF HAIR-PINS FROM THE UTERUS AND RECTUM.

Dr. W. R. Adamson, of 709 Madison Avenue, relates the case of a married woman who had introduced a hair-pin into the uterus for the purpose of inducing abortion. The object remained there eight or ten days, before any attempt at extraction was made. The os having been dilated, a silver catheter was introduced, and, guided by the index finger, its end was slipped over one leg of the hair-pin. The other leg being then seized by a pair of forceps, the body was easily removed. In another case the writer was shown a girl, twelve years of age, who had passed a hair-pin into the rectum a few hours previously. Chloroform having been administered, the sphincter was stretched, and the hair-pin was then found lodged at right angles to the gut, with one leg im-

bedded in the mucous membrane. A catheter was passed over the free leg, as in the former case, and then by pushing on the instrument the other leg was dislodged. This was now grasped by the forceps and extracted. Both patients recovered without any after-symptoms.

LOCAL ANÆSTHESIA OF THE INTEGUMENT PRODUCED BY COCAINE.

Dr. Edward S. Peck, of 53 West Fiftieth Street, writes: "I desire to emphasize the possibility of using strong solutions of pure cocaine superficially when sutures are to be placed under the integument. A single instance will illustrate this: A lady, aged seventy-three years, was operated on by me at St. Elizabeth's Hospital for marked entropion of both lower lids, of over twenty years' existence. Unused to a hospital, among strangers, and never having undergone an operation, she shrank from anything having the element of pain, and was also somewhat sensitive in the presence of the few who witnessed the operation. Merck's solution was painted over the integument of the lid and cheek of each side four times, and after fourteen minutes a quadrilateral Gaillard's stitch was taken on each side—involving four punctures for each entropion—two of entrance and two of exit. Scarcely any pain was felt, and the steps of the operation were taken as if under anæsthesia. There was not the slightest effort at blepharospasm."

COMPOUND COMMINUTED FRACTURE OF THE RADIUS IN A WOMAN SEVENTY YEARS OF AGE—RECOVERY.

Dr. H. H. Cahill, of Jersey City, reports a case of a woman, seventy years of age, who fell down a flight of stairs, sustaining a compound comminuted fracture of the fore-arm. The broken end of the radius protruded an inch and a half from the wound. The splintered portion being removed with the bone-forceps, reduction of the fracture was obtained by extension. The wound was cleansed by a spray of carbolized arnica. four sutures were inserted, and the arm was placed on an inclined plane. For some days there was a slight elevation of temperature together with symptoms of pyæmia. The wound was kept thoroughly clean, all sloughs were removed, and carbonate of ammonia given internally. At the end of the fifth day the temperature was normal. The limb was placed in a retention splint and a Lister dressing applied. The patient continued to improve from this time and made a good recovery.

Chromidrosis.—Dr. L. M. Petrone relates in *Lo Sperimentale*, No. 10, 1884, the case of a young man of healthy antecedents, who stated that he had observed for several months an increased secretion of sweat about the axilla and pubes, and this secretion was of a pungent odor and a red color. Microscopical examination of the hairs in these regions showed vast quantities of round, red-colored micrococci. They were seen along the entire length of the hair, extending even into the follicle. A few drops of perspiration taken from the axilla and placed under the microscope, showed the same micrococci. Red perspiration loses its color gradually in absolute alcohol, but more quickly in a solution of potassa. The patient was relieved by using a five per cent. solution of caustic potash. Chloroform, ether, and carbolic acid were tried without success. From the facts in this case, and from a study of the cases recorded by other observers, Dr. Petrone concludes that the phenomenon of red perspiration is probably due to a dermatomycosis localized principally in the hairy regions of the body, the parasite of which is a red micrococcus. The disease does not appear to be contagious.

Progress of Medical Science.

Ununited Fracture of Both Bones of the Fore-arm.—At a recent meeting of the Pathological Society of Philadelphia, Dr. Charles Meigs Wilson presented a specimen taken from an arm amputated about the middle of the humerus. Eight months previously, the patient, a young girl, had fallen from a window, sustaining an oblique fracture of both ulna and radius, that of the ulna being about an inch and a half, and that of the radius two inches and a half below the elbow-joint. The arm was the seat of several large ulcers, and there were also many sinuses. The probe showed the presence of dead bone. The specimen showed that there had been no attempt at union in the radius, but the comminuted fragments, being attached to periosteum, had not been destroyed. There had been a slight union of the ulna. The cartilages had been destroyed, the joint contained pus, and there was caries of the internal condyle of the humerus. The patient made an excellent recovery after the amputation had been performed.

Death from Chicken-pox.—Dr. I. V. Wichmann relates in the *Nordiskt Medicinskt Arkiv*, vol. 16, No. 3, 1884, the following case: A well-nourished infant, eight months old, was seized, nineteen days after exposure to varicella, with a vesicular eruption limited to the neck and left scapular region. The appearance of the eruption was preceded for a few days by malaise. The mucous surfaces were unaffected. The child was feverish and restless, and after eight or nine days of illness passed into a state of collapse and died. There were no signs of meningitis or of disease of the thoracic or abdominal organs. The autopsy gave negative results, with the exception of a little grayish discoloration of the cortical substance of the kidneys. There could be no doubt of the diagnosis, as there were at the time no cases of small-pox in Copenhagen, and the disease from which the child died was not communicated to any of its adult attendants.

The Presence of Sugar in the Urine of Healthy Individuals after the Ingestion of Carbohydrates.—Dr. Worm Müller writes in the *Nordiskt Medicinskt Arkiv.*, vol. 16, 1884, giving an account of some experiments made by him to determine the influence of the ingestion of carbohydrates upon the presence of sugar in the urine in healthy individuals. With this object he gave to some healthy students, from five to fifteen minutes before breakfast, cooked starch, cane-sugar, milk-sugar, grape-sugar, and honey. The ingestion of starch was never followed by any trace of sugar in the urine. After that of cane-sugar there was found cane-sugar, but neither grape-sugar nor levulose. Sugar-of-milk and grape-sugar gave only the same substances respectively. In one experiment, after three ounces of grape-sugar had been taken, none at all was found in the urine. In the trials made with honey, grape-sugar was found, but not a trace of levulose. There is thus reason for doubting that levulose is excreted by the kidneys of healthy persons after its ingestion. The author observes that these results possess some practical importance as regards the theory of glycosuria and diabetes.

A Test for Sugar in the Urine.—Dr. W. S. Groom, of Britt, Ia., writes: "I send you a test for sugar which I have never seen published, and which, for simplicity and accuracy, is not to be surpassed by Trommer's, Fehling's, or even by the fermentation test. A small portion of the suspected fluid is placed on a piece of bright tin, which is held over a spirit-lamp until the urine is evaporated. If sugar be present, the last portion of the urine will give the characteristic appearance and odor of burnt molasses. The ease with which this test can be made will commend it to the busy practitioner at the bedside."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 17, 1885.

RECENT CONTRIBUTIONS TO THE SUBJECT OF GERMICIDES.

THE study of the different characteristics of particular micro-organisms shows that agents which destroy the life of one form may not affect seriously that of another. Consequently the term disinfectant or germicide becomes a very indefinite one. Recent investigation is tending to solve the problem as to what are the best germicides for each pathogenic or putrefactive organism. Those for the ordinary bacteria of putrefaction are quite well known, and we have at different times published results of the investigations into the germicides of the various bacilli. Drs. Schill and Fischer, in a communication to the Imperial Board of Health of Germany, have shown how peculiar is the action of disinfectants upon the phthisical sputa. Carbolic acid, in a five per cent. solution, acts vigorously and destructively upon the bacilli; corrosive sublimate, on the other hand, even in a two per cent. solution, is very untrustworthy. Heat was also found to be a sure method of destroying the bacilli and spores.

Dr. Miquel has published in *l'Annuaire Météorologique de Montsouris* the results of some experiments made to determine the minimum amount of a disinfectant necessary to prevent fermentation in a litre of sterilized beef-broth. His experiments show that the mercurials are the best antiseptics, and that the biniodide is nearly three times as strong as the bichloride. This will be seen by the following table:

	Grammes.		Grammes.
Biiodure de mercure..	0.025	Chlorure de zinc.....	1.90
Iodure d'argent	0.030	Acides azotique, chlorhydrique, phosphorique et sulfurique.	2 à 3.00
Eau oxygénée.....	0.050		
Bichlorure de mercure	0.070	Acide phénique.....	3.00
Acide chromique	0.20	Permanganate de potasse.....	3.50
Chlore.....	0.25		
Iode	0.25	Acide borique.....	7.50
Brome	0.60	Sulfate de fer.....	11.00
Iodoforme	0.60	Borate de soude.....	70.00
Chloroforme	0.80	Sel marin	165.00
Sulfate de cuivre	0.90	Glycerine	225.00
Acide salicylique.....	1.00		
Cyanure de potassium	1.20		

The important fact is thus apparently shown that bacterial life is impossible in a solution containing one forty-thousandth part of biniodide of mercury, or one fourteen-thousandth part of the bichloride.

Mr. Wynter Blyth has just published in the "Proceedings of the Royal Society of Edinburgh" the results of an important research in this same direction. He endeavored to determine the relative power of different disinfectants in arresting the growth and destroying the spores of anthrax bacilli. His conclusions, as given in the *Lancet*, are mainly as follows: A one per cent. solution of pure carbolic acid in water, seemed to have no influence on anthrax spores, not even delaying their growth. Even after soaking for twenty-four hours in a ten per cent. solution of carbolic acid, the anthrax spores inoculated into a guinea-pig killed it in two days, with typical anthrax poisoning. Spores soaked for twenty-four hours in undiluted carbolic acid did not afterward develop, but they did so after six hours' soaking in a twenty-five per cent. solution in alcohol. The sulphates of iron, copper, and zinc, which are reputed disinfectants, in no case exercised any destructive influence on the life of anthrax spores. Of chloride of zinc, Dr. Koch has given a very unfavorable verdict as a disinfectant; and, as a germicide, Dr. Blyth testifies no more favorably of it. He found that anthrax spores grew well, after a month's sojourn in a five per cent. solution of chloride of zinc; and the addition of thymol in no way altered the result. Perchloride of iron was experimented with in watery solutions of various strengths, from one to twenty-five per cent.; but in no single case did a twenty-four hours' steeping of the spores destroy their vitality. Mr. Wynter Blyth's research suggests doubts as to the germicidal power of the antiseptics and disinfectants in ordinary use.

Dr. Sternberg has diligently collected nearly all that has so far been learned regarding germicides, and has added much by his own special investigations. A perusal of his work will show that there prevail a good many delusions regarding antiseptics. Attention has been called to some of these by "Medicus," who says:

"Carbolic acid (1 to 200) kills bacteria in pure fluids, and septic germs in active growth, but a ten per cent. solution will not kill them in putrid fluids. Dissolved in alcohol or oil it is useless, and will not kill germs in a hundred and ten days. It is far less useful than is usually supposed, and is fast losing its once great reputation.

"Ammonia does not destroy virus or germs or spores, and all its salts are useless as germicides; especially is the very impure ammonia of manure heaps, stables, stable and privy pits harmful. Sulphate of copper destroys the virulence of septicæmic blood, 1 to 400; it has the highest average of all the common metallic salts, except mercury, and is vastly more useful than sulphate of iron or so-called copperas, which is so largely depended upon by health officers.

"Sulphate of iron, even in saturated solution, does not kill any germs or spores, and Dr. Sternberg says, 'to use this agent as a disinfectant would evidently be a serious error.' It was first used in 1854, on account of the small portion of sulphuric acid in it. It and carbolic acid have failed again and again and yet again to prevent the spread of yellow and typhoid fevers, cholera, filth dysentery, etc., and at one time came near throwing discredit on all disinfectants. They are still largely used for privy vault disinfection, the smells of which they only cover up for a few days, but the germs in which they do not destroy. Muriated tincture of iron in four per cent. so-

lution failed to kill bacteria, yet it is largely depended upon in the treatment of diphtheria.

"Hyposulphite of soda gives no evidence of germicide power in disease. It prevents the growth of the yeast plant, but not of bacteria. Sulphite of soda is also useless."

THE PATHOLOGY OF CANCER.

MR. W. S. SAVORY'S "Bradshawe Lecture on the Pathology of Cancer" at the College of Surgeons, London, partook more of the nature of a scientific thesis than of a lecture. As might be expected, it bore traces of long thought and patient study.

Referring to the terms "homologous" and "heterologous" he remarked that the latter was commonly employed to signify tumors which do not in their structure resemble any of the normal tissues of the body. For "normal tissues" he would substitute "adult tissues," for heterologous did resemble in structure some of the natural tissues of the body when in an embryonic or immature state.

The power of attaining a high grade of development and the power of reproduction were, both in tissues and individuals, in inverse ratio. Also, the lower the grade of development the greater was the power, not only of reproduction, but of endurance of life. In proportion to the changes through which any individual or tissue passed in development, not only was its subsequent power of reproduction limited but also its maintenance of life dependent on the special conditions under which it existed.

Tumors, however various in structure, invariably consisted of one or more of the simpler tissues. The structure of cancer and its allies was characterized by the presence of the lowest and simplest of living forms. The so-called cancer-cells, the structural elements of cancer, were the very type of the rudimentary or embryonic form of tissue. Beyond this early stage the typical cancer-cell seemed never to pass. Both in positive and negative characters it corresponded with the simple animal or vegetable cell.

Those of us who have been brought up to implicitly believe in the cell-theory, were somewhat taken aback at the ruthless manner in which Mr. Savory cast it aside. He remarked that it had been shown that in the development of muscular fibres cells had no share. The ingenious scheme had been devised of modifying the definition of a cell so as to make it include structures which have no fair claim to the title of cell. The existence of a wall or limitary membrane as an integral part of a cell had been quietly ignored, but, said Mr. Savory, no better reasons could be given for applying to such a structure the term cell than that some such compromise was essential to the maintenance of a cell theory. He maintained that the cell theory, as long understood by us, was no longer tenable, and suggested that the throwing over an exploded doctrine was preferable to the confusion inevitably resulting from a vague and inaccurate use of words.

The changes which the tissues undergo after death were then referred to. It had been too hastily concluded that the characters presented by tissues after death, and even after treatment by powerful reagents, were those natural to them during life. This applied specially to cancer. During life, its elements were not differentiated even into complete cells. When fresh and unaltered, there was no distinction of cell-wall and cell-contents. In the living particle, said the lecturer, he doubted whether there was even a nucleus. In short, the "cancer-cells" were but living particles of protoplasm, equal to, but not higher than, the amœba or white blood-cell, or the utricle of the plant.

We had been taught that cancer, strictly speaking, was the outcome of the epithelial tissues. But mature epithelium was undoubtedly composed of cells showing distinctly both cell-wall and nucleus. Yet even here, development into a complete cell was through the shortest and simplest changes. In contrast, these fragments of cancer protoplasm were but the embryonic or rudimentary form of a cell of epithelium. Their power of individual development did not reach even to this level. Judge then what their power of endurance and multiplication must be.

Seeing that no satisfactory explanation of the clinical facts of cancer could be given by way of the constitution or blood or germ, some had sought to find it in the mobility and dispersion of the cells. But when we studied malignant tumors as a class, and compared them with innocent ones, it could not be affirmed that there was anything like a constant relation between the rate and extent of their distribution and the mobility of their cells.

The phenomena of cancer could not be adequately explained by any reference to the constitution in any of the senses in which the word constitutional had been employed. Neither could the clinical facts of cancer be explained by regarding it as an affection of the mass of the blood. Nor could its malignancy be explained by the mere mobility of its elements, for that was going on everywhere. All fluids and all solids were in continual motion. We might freely grant to cancer great mobility of its elements. But to explain its clinical facts we require much more. Mr. Savory said he believed what was wanting here was to be found in the nature and vital attributes of its so-called cells, or of the formless plasm out of which they come. This matter possessed an ability of living after the fashion of the lowest and simplest forms of life. When we call these structures embryonic, it must never be forgotten or overlooked that this term has reference only to their position in the scale of life, to their grade of development. They resembled embryonic substances in the simplicity of their physical characters, but they differed in the widest possible way from them in their vital attributes and life history, and in the almost, if not quite, complete absence of change of structure or of endowment. The great feature of embryonic tissues was in the advance from a simpler to a more complex state—to the formation of a higher structure with more special functions. Their great vital endowment was the power of development. But the protoplasm and fragments of cancer were just what they were, because they have none others. They could not "rise to higher things," and, according to a law of nature, obstinately retained life, and, in unbroken force, the power of propagation. Their power of growth was inversely to their power of development, and growth here was synonymous with multiplication. Upon their growth followed their dissemination.

THE PROGRESS OF THE METRIC SYSTEM.

A BILL to establish the metric system of weights and measures in the departments of the United States Government was introduced into Congress last June, and will be pressed again during the coming winter. The Committee on the Metric System of the Boston Society of Civil Engineers has recently made a report calling attention to this bill, and presenting various facts showing a continual expansion in the practical use of the metric system. We are told that electrical science now has its units: volt, ohm, ampere, etc., founded on the metric system. Another step preparatory to the free use of the metric system is the publication in metric measure of such reference books and tables of data as are commonly used in various professions and trades.

A further indication in this direction is the frequent use of metric language in the cyclopædias of recent date. This is especially shown in the "British Encyclopædia."

In the medical sciences the adoption of the metric system has become very universal, and there are few standard works on these branches in which metric terms are not used. In medical practice it is different. Very little progress has been made of late, and possibly some ground has been lost. Neither is it to be expected that there will be much change for some time to come. The uniform use of the decimal system in scientific work will eventually, however, tell upon the practical arts. Already the physician must know the metric system, even if he does not employ it in prescription-writing.

THE EXTERNAL USE OF CHLOROFORM IN LABOR.

THE Chicago *Medical Journal and Examiner* calls attention to a peculiar method of using chloroform in labor, which originated, it is said, with Dr. A. Svanberg, of Sweden. This doctor claims to have found that, in severe cases of labor where rigidity of the os has caused an obstacle to delivery, the external use of chloroform is very advantageous. His method consists in applying a piece of flannel soaked in a mixture of chloroform and sweet-oil (one to one or two to one) to the abdomen between the symphysis and navel. Then by light strokes over the cloth he makes sure that it is close to the skin. In severe cases (after five minutes) he pours on more of the mixture. After from five to twenty minutes Dr. Svanberg always finds that the rigidity is so much lessened that any desired manipulations, such as turning, may be performed.

Five cases are reported, illustrating the efficacy of this measure.

In December, 1877, he, with three other doctors, was called to a labor, in a primapara, rachitic, with small pelvis, transverse presentation, with arm protruding. The uterus was firmly contracted around the fœtus, and it was impossible to pass the hand into it, with the view of turning. She was completely anæsthetized, and continued thus for more than an hour without result. A warm bath was given, then again chloroform, but all in vain. At last he proposed to try chloroform externally, and in about fifteen minutes he could proceed with the turning.

This practice of applying chloroform externally in order to relax the parts and permit the introduction of the hand or instruments, is especially recommended to country doctors who have no assistant to give the anæsthetic by inhalation. It is not believed that it will succeed in very severe cases. It is probable that the patient practically gets a good deal of chloroform internally by this method.

THE PREVALENCE OF ARSENIC IN ARTICLES OF DOMESTIC USE.

IN 1872 Dr. F. W. Draper, of Boston, made a most exhaustive investigation of the "Evil Effects of the Use of Arsenic in Certain Green Colors," and published his results in the annual report of the Massachusetts State Board of Health. In a supplement to the last annual report of the same Board, Professor Edward S. Wood takes up the subject again, and adds numerous important facts regarding it.

Professor Wood shows that arsenic is found in many other colors than green, and that poisonous pigments are much more extensively used than has been supposed. Briefly, the principal substances containing arsenic are as follows:

1. Wall-papers. The blue and red contain arsenic oftener than the green, and even the white may have arsenic in the sizing or paste. The amount in thirty-six specimens examined averages about two or three grains (a lethal dose) to the square yard, and ranges from .59 grain to 40.7 grains per square yard.

2. "Glazed and plated" papers, used in wrapping confectionery, covering boxes, in the manufacture of tickets and playing cards, and used by children in kindergarten schools. These papers may contain all the way from one to forty grains of arsenious acid to the square foot.

3. Articles of clothing, such as green tarlatan, Foulard cambric; red, magenta, and brown stockings; green and maroon flannel, bed hangings, and paper collars. A dress examined was found to have 0.291 gramme of arsenious acid to the square metre, and a paper collar had ten grains of the same poison. Cretonnes, lambrequins, and chintz have been found to contain arsenic.

4. Articles of food and domestic use. Confectionery. The only pigment which has caused poisoning here is the green, and there are but rare instances of even this character, owing to the small amount of the substance required to produce the coloring. Bibulous fly-paper contains arsenic, as do certain moth-exterminators, rat-killers, and Paris green and London purple used against potato-bugs.

We regret that Professor Wood has not been able to give some general idea as to the absolute frequency of arsenical poisoning from the sources he has described.

So far as one can judge from facts already collected, it is only wall-paper which practically does much harm, and even here most of the reported cases are from foreign observers. Among forty-two cases cited, thirty-one are those of chronic arsenical poisoning from wall-papers. Cases are also reported illustrating local or general poisoning from playing-cards, gloves, bed-hangings, stockings, dresses, and arsenical paints.

The symptoms produced necessarily vary in severity and character. In the milder forms, there are catarrhal troubles of the eyes, nose, throat, and stomach, with headache and malaise. A condition of nervous prostra-

tion may finally result. In severer types, violent pains in the bowels, diarrhœa, vomiting, chills, and great general weakness are observed. Deaths from poisoning by arsenical wall-papers are reported.

Despite the attention which has been called to the subject, there exist as yet no regulating laws in this country as to the employment of arsenic. Such laws have been enacted, however, in most of the countries of Europe, and our State legislatures would do well to imitate them. Meanwhile, physicians should bear in mind that almost any colored wall-paper may contain a dangerous amount of arsenic.

THE LATEST ANTI-VACCINATION ARGUMENT.

In the *Lyon Médical* of October 26, 1884, Dr. Diday publishes the history of a rather remarkable vaccination. The subject was a female child one year of age. The virus was taken from the calf, and was said to have been quite fresh. It was inserted into the thigh in two different places. The vaccination took, and all went well until about sixty days after the operation, when it was discovered that several complete circles of coarse red hair, resembling that of a cow, and about a quarter of an inch in length, had grown about the cicatrix. Upon examination of the vaccine which had been left over, several very short but distinct hairs were observed, as though caught between the blades of the *porte vaccin*.

The author was eager to have the remnant tried at once upon his bald spot, but was deterred by a brother physician, and possibly by the color of the cow's hair. He kindly leaves to others the honor of founding a new method of capillary regeneration, and asks, "What will the child's fate be?" The possibilities suggested are somewhat appalling. It causes us to fairly shudder when we think of the lengths to which this transmitted bovine tendency may go. It is now evident that we have in the virus, taken directly from the calf, much more to dread than we had in the humanized crust.

To transmit almost all the known diseases of man, his bodily taints, and vicious tendencies, was quite bad enough, but to prick into the limb of an innocent child that which will change its whole nature, and cause it to grow an animal hide, is a much more nefarious form of brutality.

It is to be regretted that we are not informed whether the virus was supplied by a bull-calf or a heifer. The age of puberty of the unfortunate victim will be eagerly awaited to decide various important issues. Dr. Diday will undoubtedly record the earliest appearance of the horns, and give us a full account of the various transitions from the human to the bovine type. At any rate even the most incredulous will now be warned against incurring such tremendous risks as have been here indicated. It may seem hard to part with our old friend, bovine vaccination. But rather than have our innocent children metamorphosed into calves, we will consign this barbarous procedure to eternal oblivion.

THE MEDICAL DEPARTMENT OF THE NAVY.

The annual report of Surgeon-General F. M. Gunnell, of the Navy, is very brief, but contains several items of much interest. Considerable attention has of late been drawn to the Naval Medical Bureau, on account of certain frauds which have been discovered in its accounts. Concerning these the Surgeon-General says that an examination into the accounts instituted February 7, 1884, resulted in the discovery of a large number of fraudulent vouchers, amounting to many thousand dollars. The examination of the business of the office has continued until the present time and is still in progress, and it is not yet possible to state what is the sum of the loss to the Government.

Many of these vouchers, says the Surgeon-General, are evidently and entirely fraudulent, being for articles never needed nor delivered. Others appear to have been raised in amount after passing through the office in regular form of approval for some articles actually ordered for purchase.

From the records of the office it appears that since February, 1880, all purchases have been made directly by the Bureau, and the neglect of the usual precaution of requiring from an inspecting and receiving officer the certificate on the face of public bills, of the delivery of goods, etc., has afforded the principal opportunity for such plunder.

The investigation, we are glad to learn, results in casting no imputation upon the *personnel* or general management of the Medical Bureau.

For several years it has been the policy of this Department to encourage researches in sanitation. One of the results has been the establishment of a Museum of Hygiene, which has already become an institution of much scientific interest and practical importance. During the past year 240 articles for exhibition have been received, making a total of 650 in the collection. The number of bound volumes added to the library during the same time was 1,839, making a total of 7,049. A well-equipped experimental laboratory, with photographic and microscopic apparatus, is connected with the museum.

The Surgeon-General urges the advisability of giving opportunities to the naval medical officers of taking post-graduate courses in the various schools at Boston, New York, and Philadelphia.

The ratio of mortality in the naval service for the year 1883 was 4.55 per thousand of force, the total force afloat being 9,874. The number of admissions for sickness was 8,550.

The Bacillus of Syphilis in Syphilitic Lung Disease. As in a measure confirmatory of the announcement by Dr. Lustgarten of a bacillus of syphilis, Dr. Koeniger, in the *Deutsch. Med. Wochensch.*, No. 50, states that in examining the sputa of certain cases of lung disease, where the tubercle bacilli were absent, he detected groups of long and delicate rod-shaped organisms differing in their staining reactions from the tubercle bacillus, and about twice as long as the latter. Two of the six cases in which these micro-organisms occurred were undoubtedly syphilitic, and further inquiry in two other of the cases showed that they also had been exposed to syphilitic infection. The fifth case was that of a lady, who had the history of having had many abortions, while in the sixth there was no history of syphilis whatever. Dr. Koeniger has not added very much to the subject as yet.

News of the Week.

Dr. Ambrose L. Ranney, Professor of Applied Anatomy in the Post-Graduate Medical School of this city, has been appointed to fill the Chair of Anatomy in the Medical Department of the University of Vermont, rendered vacant by the death of Professor Darling.

New York Pathological Society.—The following officers have been elected for the ensuing year: President, Dr. John A. Wyeth; Vice-President, Dr. George L. Peabody; Secretary, Dr. Wesley M. Carpenter; Treasurer, Dr. John H. Hinton; Editor of Transactions, Dr. John A. Peters; Assistant Editor, Dr. Frank Ferguson.

The Malignancy of Syphilis.—Dr. F. S. Hillbish, of Fremont, O., writes: "Noticing the death of Dr. Atkinson in a recent issue of The Record, and of his death being ascribed to malignant syphilis, the question presents itself to me, whether it is so much due to the malignancy of the disease, as it is due to the susceptibility of the person that is inoculated, or to the great mental or physical exertion one may undergo during the *active stage* of the disease? A case in point: H. L——, forty years of age; weight, 180; a man of great endurance, while away from home in March, 1884, contracted syphilis. His health before that had always been good. The chancre was cauterized, and the patient put upon the use of proto-iodide of mercury by the physician he consulted. He continued at his occupation of lumberman the while. The disease progressed its usual course, though with increased severity in some of its symptoms, such as the eruption of the skin, which showed itself in large, raised, red blotches, one-half to one inch in diameter, that would suppurate slightly and then cicatrize. He came home in July, and worked hard storing his grain during the harvest. On July 27th he became hemiplegic on left side, with a tendency to sleep and some delirium; on the 30th he was comatose, with contracted pupils and stertorous breathing, etc. Under large doses of elaterium he became conscious in thirty-six hours, and under daily inunctions of blue ointment, 3 j. in each rubbing, for twenty days, the paralysis disappeared, the mind was bright, the blotches of the skin had all healed. Oleate of mercury was then substituted, and used at intervals of a day or two. On August 27th he again became semi-comatose and hemiplegic. He was again given a dose or two of elaterium, but without the same effect. He was then daily rubbed with blue ointment, 3 j. each time for five weeks. Since then have allowed an interval of a day or two to intervene, as the gums seemed to get somewhat sore and tender. On November 10th, iodide of potassium was given three times a day in five-grain doses, and gradually increased, so that he is taking now twenty-five grains three times a day, and an inunction of mercury on every third day. I will say that potassium iodide had been tried earlier, but it made his head ache. Under the above course he has gradually improved, so that he can, with the aid of a crutch, get around quite well. The arm is as yet of little use. With the great deal of mercury that has been used in this case his nutrition has not suffered to any appreciable extent."

The British Gynecological Society is the title of a new society recently organized in London. Its first officers are: Honorary President, Dr. R. Barnes; President, Dr. Alfred Meadows; Vice-Presidents, Drs. Aveling, Bantock, Kidd, Routh, Simpson, Pr. Smith and Tait; Secretaries, Drs. F. Barnes and Heywood Smith.

The Deaths from Snake-Bites in British India alone, in the year 1882, were 19,519, a larger number than ever before reported.

Boston Medical Library.—According to the Ninth Annual Report of the Boston Medical Library Association, the collection now embraces 14,699 volumes and 12,289 pamphlets, the increase being at the rate of nearly 1,600 volumes a year; and 328 journals and transactions are received regularly. The entire library is now available for consultation.

The Lacaze Prize of $2,000 has been given to M. Debove for his "Leçons sur la Tuberculose Parasitaire."

Prophylaxis against Phthisical Infection.—The Austrian Minister of the Interior has issued directions to the hospital authorities to the effect that they adopt proper regulations for the prevention of phthisical infection in the hospitals.

Three Odes to the Bacillus have already been written, but none to Koch.

Peripatetic Female Gynecologists.—A correspondent of the *Australasian Medical Gazette*, writing from Northern Queensland, says: "An American lady has been publicly lecturing here on diseases of women, to ladies who can afford to pay five shillings for admission; she also advertised that she could be consulted free of charge, but then she sold uterine supporters at the same time at an exorbitant price. I sent my wife to two lectures from curiosity, but I could not induce her to hear any more. The lectures, two of which were free, were for ladies only, and the lecturess explained to her audience how they could examine themselves to find out if they had any disease of the womb. Girls of from thirteen years upward, only some of whom were accompanied by their mothers, were present to listen to these abominable exhibitions—for such they were, as a great number of models and diagrams of female diseases were shown."

"A Simple Expedient in the Management of Strangulated Hernia."—Dr. C. A. Stewart, of Chicago, writes that he is the author of the above communication, which appeared in The Record recently.

Some Delusions Regarding Disinfectants.—A lecture on "Disease Germs" was delivered in this city last week by Dr. George M. Sternberg, U.S.A., at the College of the City of New York. He criticised certain of the popular modes of disinfection. Some of the measures of disinfecting, he said, still recommended, so far as any real value is concerned, may be classed with the charms and incantations of superstitious savages, or to the solemn processions and religious ceremonies which in some countries are relied upon to arrest the progress of pestilential maladies. The flannel rag saturated with carbolic acid and hung up in the sick-room and the chlorine saucer placed underneath the bed are as impotent as the songs of the savages or the ceremonies of

the heathen. Such measures only do harm by leading people to neglect the far more important measure of admitting an abundance of fresh air, by which the disease germs may be wafted away and finally destroyed. The sulphate of iron, sulphate of zinc, carbolic acid, and numerous proprietary disinfectants in the market, although valuable as antiseptics or as deodorizers, are untrustworthy for the destruction of germs. In their place Dr. Sternberg recommended half a dozen other disinfectants, among them liquor sodæ chlorinata, which he considered far superior to many much-lauded germicides now in the market.

The Medical Department of the University of Nebraska.—Some time ago we made certain criticisms upon the new medical college recently organized at Lincoln, Neb., a city of thirteen thousand inhabitants. We have received a letter from the Chancellor, who desires to correct certain misapprehensions regarding the institution in question. He states that the college is not in the hands of eclectics, but that its Faculty consists of nine regular professors and three lecturers, with three homœopathic and two eclectic professors. The Nebraska *Medical Journal* is not the organ of the college, but its editor happens to hold one of the eclectic professorships. Our correspondent does not explain how it was that this editor, as Dean of said college, distributed circulars begging piteously for students somewhat over a year ago.

A State Board of Medical Examiners of North Carolina, its members appointed by the State Medical Society, has been in existence since 1859. No person can practise medicine or surgery without a license from this Board. Although the law provides no penalties, a recent report states that it has accomplished good results in weeding out quacks and forming a healthy public opinion regarding that class.

Dr. Edward N. Brush, of the Utica Asylum, formerly of Buffalo, has been appointed to the charge of the male department of the Pennsylvania Hospital for the Insane.

Another Medical Centenarian.—Dr. O. S. Taylor, of Auburn, N. Y., completed his one hundredth year on December 17th. He graduated from Dartmouth College in 1809, and from the Medical College in 1813.

The Cholera in Italy.—According to official reports there were 17,300 cases of cholera in Italy during the recent epidemic, with 8,600 deaths, giving a mortality of about 50 per cent. This hardly sustains the view advanced by some that cholera is becoming less malignant.

Another Non-Restraint Asylum.—Dr. Peter Bryce announces in his last biennial report of the Alabama Insane Asylum that for two years the use of mechanical restraint has been abolished in that institution. The results have been favorable beyond expectation, and Dr. Bryce is enthusiastic in advocating the new method. With such testimony continually coming in, what can be said of the dulness and insincerity with which this question is still met at Utica and other American institutions, which are stealthily reducing restraint without having the candor to acknowledge any change of opinion.

Italian Physicians on the Contagiousness of Phthisis.—The Italian Society of Public Hygiene has recently instituted an inquiry as to the contagiousness of phthisis. There were 680 replies received from medical men. Of these 59, or 8.6 per cent., believed in contagion; 124, or 18.2 per cent., denied it, and 497, or 73 per cent., admitted the necessity of other causes, especially heredity.

The Kansas State Medical Society meets at Topeka on January 20th.

Odd Expressions are sometimes made by authors. In the last New York Medical Record a physician mentions that "Dr. Osio lost three eyes by panophthalmitis." Three-eyed medical gentlemen are so scarce in this world that the doctor's mishap takes on the proportions of a public calamity.—*Evening Post.*

Marriage and Cholera.—Some one has discovered that in the recent epidemic of cholera in France marriage furnished a certain amount of protection against the disease. Three times as many unmarried as married men were attacked. The fact is expected to give a great impulse to matrimony, and some of our far-sighted obstetricians have been seen to smile.

The Hospital Saturday and Sunday Collection.—The latest report given by the Treasurer, Mr. Charles Lanier, states that the amount of money collected is $22,655.53.

The Frauds in the Naval Medical Department.—An event which has never before occurred in the history of the navy is the assembling in Washington of fourteen of the fifteen medical directors of the navy as witnesses in the fraudulent voucher cases of the Bureau of Medicine and Surgery of the Navy Department.

The Oldest Disease in the World.—Busk has discovered osteo-arthritic lesions in bones found at Gibraltar, which must have belonged to bears of the glacial period.

Death from a Patent Medicine.—A young woman of Weymouth, England, recently committed suicide by taking three bottles of chlorodyne. The jury recommended that chlorodyne should be placed among the poisons not salable except upon prescription.

Resurrecting Bacilli.—According to *Wratsch*, Professors Iwanonski and Winogradow have discovered comma-bacilli in preparations of cholera-intestine made by the late Professor Rudnew eighteen years ago.

Dr. Richardson's Lethal Chamber.—Dr. Richardson, of London, has devised a chamber for purposes of canine and feline euthanasia. In this apartment, at the Dogs' Home, over six thousand dogs have during the past seven months slept their final sleep. The principal agent used for the narcotic action is carbonic oxide, passing, at summer heat, over a mixture of chloroform and carbon bisulphide into a lethal chamber, in which chamber as many as one hundred dogs can at once receive euthanasia. This is on the large scale; but Dr. Richardson describes also a small apparatus which, after long trials, he has completed, in which from one to six animals can be painlessly killed, and which is so portable that it can be wheeled from a central station to any

house or street ready for immediate use. We very much doubt if Dr. Richardson's lethal chamber is as quick, cheap, and painless as the method of drowning used in this city. But then it is more scientific, and possibly the dog may feel an additional euthanasiac thrill at receiving his quietus *secundum artem*.

A Medical Students' Society has been established in Paris. The number matriculated this year is 3,994, of whom 127 are Americans, and 22 English.

To Abort Facial Erysipelas Professor Da Costa has successfully used hypodermic injections of muriate of pilocarpin (gr. $\frac{1}{4}$ to $\frac{1}{6}$), repeated if necessary.

Reviews and Notices.

The Elements of Pathology. By Edward Rindfleisch, M.D. Translated from the First German Edition by W. A. Mercur, M.D. Revised by James Tyson, M.D. Philadelphia: P. Blakiston, Son & Co. 1884.

The author's aim in the preparation of this little volume has been to establish a "natural ground work" of pathology, and to place that science in as clear a light as possible. It can hardly be said that this task has been successfully accomplished. On the contrary, mooted questions are made, if anything, just a trifle more obscure than they were before the publication of this new work. It is not a volume to be recommended to students or beginners. The physician, however, who is already conversant with pathology in its modern developments, will read Rindfleisch's views with profit quite often, with interest always. But he will probably differ from the distinguished author in more points than one.

A Practical Treatise on Disease in Children. By Eustace Smith, M.D., M.R.C.P., etc. 8vo, pp. 844. New York: William Wood & Co. 1884.

Some books are read because of the celebrity of the author; some on account of their novelty; others for their merit; still others for the attractiveness of their style. The book of Dr. Eustace Smith combines all the reasons for commanding attention; it will therefore be read and, what is more, studied and remembered. It is exactly what the title terms it: a *practical* treatise on disease *in* children. All other works devoted to the special consideration of this branch of practice speak of diseases *of* children, as we speak of diseases of women, just as if children were subject to diseases which were peculiar to them; whereas, they suffer from the same diseases as adults, but deserve especial study, nevertheless, because these diseases assume *in* them different features, owing to their anatomical and physiological idiosyncrasies. The treatise is also practical; it is not burdened with excess of pathology and morbid anatomy, but while giving sufficient to elucidate the nature of the structural changes produced, it devotes the greater portion of the space to diagnosis and treatment.

The work consists of twelve parts: the first three are devoted to the study of the acute infectious diseases, general diseases not infectious, and diathetic diseases respectively, while each of the remaining nine treats of the diseases of some particular organ or group of organs. The work as a whole, and the separate parts, are each, in most instances, introduced by a chapter of introductory remarks, which constitutes by itself a most valuable and useful essay, giving general considerations appertaining to the peculiarities of function, disorder, and treatment of the parts about to be considered. This is followed by an elucidation of the particular group of diseases, which, with few exceptions, for clearness, comprehensiveness, and practicability, leaves little or nothing to be desired. Another characteristic of the author's style is its logical consecutiveness; the chapter devoted to the consideration of a certain disease is not merely a succession of statements joined together by mere juxtaposition, as we too often see in medical or other scientific works, but is a coherent and connected collection of associated and interdependent phenomena properly explained and suggesting the correct mode of combating the disturbance.

The subject is brought down to date. The references, which are incorporated in the text, are not so numerous as to overshadow the main work, and are to the most recent and reliable authors in all languages. It is certainly flattering to our national pride to note the thorough familiarity of Dr. Smith with American literature; thus on one page are references to Gibney, Fruitnight, and J. Lewis Smith. While not disposed to adopt every new remedy offered, the book still supplies the latest reliable treatment for the different diseases, and while not being dogmatic, does not give such a great variety to choose from as to lead to confusion, depending principally upon the results of the author's experience. He has faith in arsenic as a prophylactic against scarlatina; is an advocate of trained nurses, especially in diphtheria; approves of white lead paint in the treatment of erysipelas, and of amyl nitrite in the relief of convulsions. Belladonna is one of his favorite remedies, and he gives it in doses which many of his readers will hesitate to try: thus he gives ten drops of the tincture to the newly-born infant, fifteen drops to one of a year, and a drachm to a child of four years. But it certainly must be a misprint when, in the treatment of intussusception (p. 676) he advises, "for a child of twelve months, one-twentieth of a grain of morphia and a *sixth* of a grain of atropine every half hour." We presume that sixtieth is intended; but if the advice as it stands were to be thoughtlessly followed, the effect would not be brilliant—at any rate in the direction desired.

The book is a model of its kind; and the publishers have given it a dress worthy of the work and of the author. The book is strongly bound, and is printed in large clear type on good paper.

Medical Diagnosis. A Manual of Clinical Methods. By J. Graham Brown, M.D., Fellow of the Royal College of Physicians of Edinburgh; Late Senior President of the Royal Medical Society of Edinburgh. Second Edition, Illustrated. New York: Bermingham & Co. 1884.

In this excellent little manual the author treats very concisely, yet thoroughly, of the various evidences of disease, grouping them under the respiratory, circulatory, digestive, and other systems. It differs from the standard treatise of Da Costa in that it does not approach the subject from the standpoint of individual diseases, but from that of isolated symptoms, showing the value and the significance of these signs, and indicating the diseases to which they point.

Lectures on Diseases of the Rectum. Delivered at the Medical Department of the University of the City of New York. By J. Williston Wright, M.D., Professor of Surgery. New York: Bermingham & Co. 1884.

These lectures were originally delivered to students attending the spring course at the University Medical College. They are now published in book form from stenographic notes, the lecture style having been preserved throughout. This, however, is no detriment to a work of this kind, which is necessarily somewhat elementary and makes no claim to be a treatise of rectal disorders, but rather adds not a little to the pleasure of reading it. All the affections of the rectum which are liable to be met with are here treated of in turn, and in a clear and pleasant manner. Although the lectures were addressed to a class of undergraduates they will be found well worthy of perusal by practitioners whose knowledge of these diseases has grown a little rusty from want of practice.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 10, 1884.

R. E. Van Gieson, M.D., Vice-President, in the Chair.

SARCOMA OF THE UTERUS.

Dr. H. C. Coe presented a specimen of sarcoma of the uterus removed at autopsy. It was interesting chiefly on account of the rarity of the disease and the progress of the case. The woman was upward of thirty years of age, married, and entered the Woman's Hospital complaining of severe pain in the lower part of the abdomen, with frequent uterine hemorrhage. The uterus was dilated, and the entire canal curetted, with the result of removing about one ounce of soft, brownish-looking material, which on examination was found to be round celled sarcoma. The patient developed pyæmia, which ran its usual course, and terminated fatally on the eighth day. About twenty-four hours before death metastatic pneumonia developed, and there was found a large abscess in the lower lobe of the right lung, with several smaller abscesses in its immediate neighborhood, infarctions of the liver, kidneys, and spleen. There was no peritonitis. There was a purulent thrombus which extended from the uterine veins on the right side upward into the right iliac vein and lower part of the ascending vena cava, which had given rise to thrombic phlebitis and periphlebitis.

Although the disease was rare, Dr. Coe had seen another specimen of like character about one week previously, in which the entire uterus was removed. Dr. Emmet had still retained the statement, in the last edition of his book, that he has seen only six cases of sarcoma of the uterus, which agreed very well with statements made by other authors. During his term of service in the Woman's Hospital, Dr. Coe had collected five cases, and was of the opinion that the disease was frequently overlooked, and that diffuse sarcoma was frequently diagnosticated as fungous degeneration of the inner surface of the uterus. In the present instance the growth was not recognized before curetting was performed.

Dr. Wyeth presented three specimens of bone removed at different operations. The first illustrated

OSTEITIS OF THE ACROMION PROCESS OF THE SCAPULA,

resulting from traumatism. The only point of interest in the specimen was the fact that the operation was performed under strict antisepsis, with the application of a permanent dressing with a bone-drain, and union took place under the single dressing, the bone-drain having entirely disappeared by absorption.

OSTEITIS OF THE KNEE-JOINT.

The second specimen consisted of several small pieces of bone which Dr. Wyeth had removed seven weeks previously from a patient thirty-six years of age, who had received an injury of the tibia in the neighborhood of the knee-joint, and which terminated in periosteitis and osteitis. After trying various methods of treatment, he cut down upon the tibia seven weeks ago and performed the operation of gouging, an operation which he favored. In performing the operation it was necessary, in order to remove all the diseased bone, to enter the knee-joint. As soon as the dead bone was removed, a piece of iodoform gauze was stuffed into the opening, and remained in position until the operation was completed. The limb was then dressed antiseptically, and the patient recovered without a single unfavorable symptom, not even a symptom of synovitis developing.

OSTEITIS OF THE UPPER EXTREMITY OF THE FEMUR.

The third specimen was all that remained of the femur above the small trochanter. It was a case of hip-joint disease from osteitis of two years' standing, and there was shortening of two inches when Dr. Wyeth first saw the patient. There was a sinus below the trochanter in the usual position, one on the inner side of the thigh, between the femoral vein and the gracilis muscle, which discharged fetid pus. Dr. Wyeth placed the patient on a tonic plan of treatment, and after improving his general condition, he removed, on the second of October last, by ordinary excision, all the diseased bone, using for that purpose the exsector which he had already exhibited to the Society. On opening into the joint he found that the epiphysis of the femur had disappeared entirely. The patient made a good recovery, and now walked on the lame foot. When the femur was pushed up into the acetabulum there was about one inch of shortening, so that new bone had formed to the extent of one inch, as there were two inches shortening before the operation was performed.

The point in the surgery of the case which Dr. Wyeth wished to make especially prominent was, that the operation for exsection of the hip-joint for hip disease was not specially dangerous. Although he had performed it but three times, all the patients had recovered from the operation. In one case death occurred four to six months afterward, and was due to other causes than to the hip-joint disease. He thought it was not surgical to delay this operation as long as was generally done, and believed that, as soon as it could be determined there was osteitis in the cancellated structure of the head of the femur, we should open into the joint and remove the diseased tissue, and by so doing he believed that the surgeon could not only prevent permanent lameness, but preserve the life of the patient and relieve him of many years of suffering.

Dr. Gibney thought that the second specimen presented by Dr. Wyeth belonged to the class of affections commonly known as tibial abscess, or osteitis of the upper epiphysis of the tibia, which was formerly, and at the present time by some operators, treated by trephining. He believed, however, that the treatment adopted by Dr. Wyeth was certainly very commendable, and it showed how by a little timely interference, by relieving swollen periosteum and bone by free incision, the joint might be saved from being disastrously diseased.

Recently he had had a case of osteitis of the tibia which ran its usual course without surgical interference, and with but little mechanical interference, because the joint did not appear to be diseased. An immense cold abscess, however, developed, and finally, about the time it was ready to open spontaneously, it had produced inflammation of the lower epiphysis of the femur, which continued, and quite recently the patient had developed osteitis of the upper part of the opposite thigh-bone. Dr. Gibney's conviction was that, had the case been treated as Dr. Wyeth had treated his, even after the abscess at the upper portion of the tibia had formed, not only would the knee-joint have been saved, but the caseous foci also would have been lessened which had probably served as a source for the development of tubercular osteitis in the opposite hip-joint.

That case led him to refer to the third specimen presented by Dr. Wyeth, and he asked whether it would not have been rational, when he first recognized the osteitis of the head of the bone, to have performed osteotomy, or igno-puncture, or some operation of like character, for the purpose of converting a chronic into an acute affection, rather than to have resorted to a radical operation of chiselling.

Dr. Wyeth replied that it was difficult to answer why not. The only objection apparent was that the hip-joint was a very deep joint. At the knee-joint gouging could be done easily, while without a free incision over the hip-joint he feared that removal of all the diseased bone by gouging could be only rarely accomplished. When the joint was laid open freely, and the diseased bone removed with the saw, the exact condition of the bone remaining

could usually be determined without difficulty. Besides, it was rare that disease of the neck of the femur extended below the trochanteric line, although it might do so, and if he had simply gouged he probably would have left foci of the disease remaining.

Dr. Wyeth fully endorsed Dr. Gibney's view concerning the gouge, or treatment with Volkmann's iron spoon, or similar operation for diseased bones about joints, and he would not say that the same methods should not be used in treatment of disease of the hip-joint.

Dr. Ripley thought it exceedingly rare for a case, such as alluded to by Dr. Gibney, one in which there was multiple disease of the joints, to occur except in a patient in whom there was a marked constitutional taint, either tubercular or syphilitic; and his position was against the idea that if the joint first diseased was operated upon at once, all subsequent trouble would probably be avoided. In such children as the one in Dr. Gibney's case, there was a predisposition to joint disease, and even if the arthritis in one joint was cured, it was likely to develop in another joint.

Dr. Garrish asked Dr. Wyeth if he would operate before suppuration had taken place.

Dr. Wyeth replied in the negative, and said that the formation of pus was an indication for the performance of the operation.

CASE OF SACRAL SPINA BIFIDA CURED AFTER INCISION OF OVERLYING PHLEGMON (?), WITH SUBSEQUENT CHRONIC HYDROCEPHALUS TREATED BY FREQUENT ASPIRATIONS.

Dr. Gibney presented a tumor from a bifid spine and the brain of a hydrocephalic spine, with the following history: A male child, seven days of age, was brought to his clinic on July 11, 1884, presenting a sacral tumor, sessile, the size of a split lemon. The skin was normal except at lower portion of tumor, where was seen a scabbed ulcer, the size of a one-cent piece. Perfect translucency in every portion. Lower limbs not deformed or paralyzed, and the child seemed normal in every other respect. Family history furnished nothing pertinent to case. Treatment was deferred for a fortnight, when he prepared to aspirate and inject the Morton solution of iodine and glycerine. Found pus, and did not inject.

Three days later patellar tendon reflexes much exaggerated, though muscular reaction to faradism in both limbs good. Temperature not elevated. Base of tumor phlegmonous.

On July 29th, under chloroform, introduced bistoury, giving exit to about a drachm or two of sero-pus, the point of bistoury striking a tumor within the one already opened. Did not open inner tumor, but dressed parts antiseptically.

Within a few days wound healed, but scattered over back was a rich crop of furunculi. Reflexes about normal. Rectum prolapsed, but was normal within a month.

August 16th, the head was observed for first time to be enlarged, and by the 23d hydrocephalus pretty well established. The bromide and the iodide, at first separately, then conjointly, failed to afford any relief.

On September 9th, aspirated the head, introducing needle in anterior fontanelle to left of longitudinal sinus, and drawing off about one ounce of clear serum. No untoward symptoms at the time observed, but three days later the lower limbs were observed to be in rigid extension. The spina bifida seemed to be cured, and indeed this gave no further anxiety. Aspirated again on October 2d, the needle this time being introduced deeply into fontanelle to right of longitudinal sinus. Amount withdrawn ʒ iij. On the 7th, five days later, aspirated, removing ʒ iij. The head was increasing slowly, despite the aspirations. On the 14th the amount withdrawn was ʒ ivss.; on the 27th, ʒ v.; on November 3d, ʒ v.; on the 8th, ʒ v.; on the 15th, ʒ vj.; on the 28th, ʒ viijss.; and on December 4th, ʒ vj. At no tapping were any alarming symptoms produced, and it was not until the 6th that the child died. It then died of asthenia. The limbs were rigid after the first tapping and so continued till death. The head had no impression apparently made upon it by the many tappings.

At the autopsy Drs. Holt and Amidon assisted. The tumor consisted of a mass of cicatricial tissue, in the bottom of which was a small cavity without fluid, but communicating through a small opening with the spinal canal. A probe passed through this between dura and arachnoid up to the beginning of the cauda equina. The laminæ of the sacral vertebræ were absent. On section of spinal column no evidence macroscopic of any inflammatory lesion within canal. Central cavity of cord not open. No evidence of myelitis.

Very little fluid—not more than three drachms—found without the cerebral mass. Convolutions much flattened. Lateral ventricles greatly distended, only the cortex of brain remaining. Three pints of fluid removed. Ependyma markedly roughened. No evidence at any point, either in brain or membranes, that any acute inflammatory process had existed. Other organs not examined.

Dr. Amidon asked Dr. Gibney if the commencement of the hydrocephalus and the appearance of the exaggerated reflexes were synchronous.

Dr. Gibney did not know. His attention was not called to the head during the two or three weeks immediately following the diminution of the reflexes.

Dr. Ripley asked whether or not there was a steady increase in the size of the head while the tappings were being performed.

Dr. Gibney replied that the size increased steadily from week to week. For a day or so after the tapping, the head seemed to be smaller, and then it would increase in size.

Dr. Ripley thought that the tapping might have been performed too often, and referred to a case reported by Bennett, in which the head was tapped three times and the child died, and the fatal result was attributed to the fact that the tapping was performed too frequently. At the same time, Bennett referred to Dr. Conquest's contribution on the subject, who published nineteen cases which he had treated by tapping, with ten recoveries. Dr. Conquests's plan was to tap not oftener than once in two weeks, and he always strapped the head after the operation. Those cases were the most successful on record. The operation of tapping for chronic hydrocephalus had not met with large success, the cases having, as a rule, terminated as had Dr. Gibney's.

Dr. Amidon asked Dr. Ripley what he regarded as recovery after tapping.

Dr. Ripley thought recovery in these children might take place to such an extent that they had a fair degree of intelligence. As to whether or not any fluid remained in the cranial cavity, it was difficult to say. He had two cases in mind, in which the patients recovered. They were treated by hyper-nutrition, and tapping was not performed. Three years had already elapsed since the children were under treatment, and one of them he saw about a week ago, when it was as bright as children ordinarily were at that age, and stood quite firmly upon its feet. In the other child the peculiar appearance of the fontanelle had disappeared and it had diminished in size, and the cranial sutures had united. In both these children there was the characteristic appearance of the eyeball, namely, rotation downward and outward.

MISSED ABORTION.

Dr. Kucher presented a placenta and fœtus, for which he was indebted to Dr. Glück. It was expelled by a woman twenty-eight years of age, the mother of two children. Menstruation ceased three months previously, and she developed the ordinary symptoms of pregnancy. At the end of six weeks there was notable increase in the size of the lower portion of the abdomen, which again markedly

diminished in size ; the increase in the size of the uterus at first corresponded to the fifth month of pregnancy, and finally to about the third month of pregnancy. The woman complained of loss of appetite and general uneasiness, and at the end of the term, with regular pains, the mass presented was expelled, which consisted of a very large placenta with an extremely small fœtal development.

The Society then went into executive session.

HARLEM MEDICAL ASSOCIATION, NEW YORK CITY.

Stated Meeting, December 11, 1884.

MALCOLM MCLEAN, M.D., PRESIDENT, IN THE CHAIR.

DR. D. C. COCKS read a paper (see page 65), entitled

A CASE OF EXTRA-UTERINE PREGNANCY, SUCCESSFULLY TREATED WITH GALVANISM.

Upon invitation, DR. A. D. ROCKWELL opened the discussion by remarking that another case of extra-uterine pregnancy, successfully treated by electricity, calls renewed attention to a method of procedure, the importance of which cannot be overestimated.

Knowledge or ignorance of its use and the methods of its application in these cases, means simply life or death to the unfortunate woman, and if this physiological accident, so to speak, could be numbered among the more common occurrences in medicine, there can be no question that such proofs as have been given of the specific character of the remedy would be heralded throughout the civilized world. On the contrary, however, the impressions upon the professional mind that have been made by the various well-authenticated published statements, reinforced by many of the most distinguished names in gynecology, such as Thomas, Emmet, Sims, and others, have been strangely restricted and incomplete. A notable illustration of this occurred but a short time since. While on my way to see a case of this character, I met a physician justly distinguished for his learning and ability, and upon mentioning the subject to him found, to my astonishment, that it was entirely new. This gentleman, to be sure, has no special interest in midwifery, but if, in one of the centres of medical progress and learning, accounts of such cases had escaped even an observant mind, how much more would they be likely to pass unnoticed by, or even fail to reach the eye of the remote thousands. Every well-authenticated case should then be given as wide a publicity as possible, the methods of diagnosis made clear, the kind of electricity used mentioned, and the character of the treatment detailed.

The author of the paper has dwelt quite fully upon the former points, and it only remains for me to speak of the treatment, and the case in hand illustrates very forcibly one point, and that is as regards the kind of electricity that is most effective.

I cannot doubt but that galvanism is preferable to faradism, and this belief is based on the teaching of experience as well as upon physical and physiological grounds. In the various cases where I have had the opportunity to operate the galvanic current has always been used, and always with speedy and complete success.

The faradic current has also been used successfully, but in the case under consideration its action seems ineffectual, and only after galvanism was resorted to did the results prove satisfactory.

There may be a tendency sometimes to use too strong currents, and as it is impossible to estimate the susceptibility of a patient at first sight, the secondary effects of such treatment may prove unpleasant. Few cases, I imagine, would ever call for more than eighteen or twenty cells, and more frequently twelve or fourteen prove sufficient. The shocks should be sharp and quick and the negative pole applied directly to the fœtal mass. Very little pain, as a rule, is caused, and only in one case did I ever observe any persistent soreness, or suggestions of inflammatory action, and these subsided in a few days.

How much of danger lies in the possibility of rupturing the already distended tube by shocks too strong and rapid it is impossible to say, but that such an accident might occur it is reasonable to suppose ; hence another and a still graver reason for moderation in the number of cells used.

When suspicions are aroused as to the existence of tubal pregnancy, the diagnosis does not seem to be so difficult as might be supposed. Almost always a suspicious enlargement can be felt per vaginam or rectum, and this, conjoined with pain over the left side and irregular discharges of blood, is sufficiently suggestive. In any event, and most fortunately, the treatment is not likely to do harm, and therefore it would seem that the thing of primary importance is that a knowledge of the efficacy of this treatment be widespread, so that every practitioner be on the alert in all cases of pregnancy, and when a case of this kind occurs, not allow his patient to die through ignorance of a simple and effective method.

In reply to Dr. Harris, Dr. Rockwell said that he preferred to use the short and sharp interrupted galvanic current, but in one case, beginning with fifteen cells with a rheostat, he had rapidly pushed up to thirty cells.

Dr. Carman asked how many applications Dr. Rockwell was accustomed to make, and was answered that he had never made above four. It was possible to kill the fœtus with one application. He had made applications every day, and could not understand why there was so great pain in the case reported. He had never been obliged to use ether.

Dr. Van Santvoord desired to know where Dr. Rockwell placed the electrodes, and was told they were placed in the rectum and vagina. It was a prevailing impression that this was a difficult surgical method, yet it was simply placing metallic balls to the growth itself.

DR. ABERNDORFER thought that it was dangerous to give ether, as it might produce sufficient vomiting and straining to rupture the sac.

DR. SANDERS said that although he was in favor of using electricity in these cases, yet it most often happened that when seen for the first time the sac had ruptured and it was a question what to do then. Tait was in favor of making an abdominal section, and had reported a number of cases in which he had performed laparotomy. He regarded all cases of extra-uterine pregnancy as tubal in the beginning, that all others had ruptured and passed into that state. Dr. Sanders had seen cases of pyosalpinx that had disappeared, and these might have been confounded with extra-uterine pregnancy. They were not rare cases, as various large reports had been made recently, but they mostly occurred in consultation practice.

DR. RICHARD remarked that the condition was not so rare, as a report of two hundred cases in four years had been made.

DR. HILLS said, I am rejoiced to know that such a remedy has been discovered. Recently I have seen the skeleton of a case that occurred many years since. The patient had gone on to full term, and there had been an attempt at expulsion. During a period of twelve years bones had been discharged, and after the patient's death more were collected.

The point to be noticed was that the case had progressed without a correct diagnosis having been made by the physician.

DR. CAMPBELL thought this was one of the gigantic steps that had been made in medical practice during the past twenty-five years. It showed that physicians needed to keep abreast of the advance that had been made.

DR. MALCOLM MCLEAN remarked that the subject of extra-uterine pregnancy must be considered as the condition exists in its several forms or stages, as the treat-

ment must be essentially different in the different conditions or stages of development. We have to deal mainly with three forms, or rather three implantations, of the ovum: 1, The tubal form; 2, the ovarian form; 3, the abdominal form.

These varieties may, of course, be divided up pathologically into several other subvarieties, such as the tubo-interstitial, etc., but practically we are interested in the three implantations mentioned. In the tubal form of this accident the ovum and tube develop together for about four weeks usually, when the tube-walls seem not to keep pace with the development of the ovum, and consequently they are stretched until they become very thin, and rupture is liable to occur in the great majority of cases about the third or fourth month. Discharge of blood and other contents of the ovum into the peritoneal cavity is the rule, and consequently violent pain, shock, and, where life is prolonged, peritonitis is the result. To avoid development of the early ovum, then, is the foundation of all good treatment, and nothing has given such brilliant results as a properly applied current of electricity. It has been shown that the galvanic current of about eighteen or twenty cells is the best form of electricity for this purpose. The experience of many physicians has proven that in this remedy we have a safe and sure means of cutting short these dangerous cases, and all other operations must fall almost out of consideration in connection with extra-uterine pregnancy of under four months. Should any other operation or remedy, with so little risk attached to it, accomplish such flattering results in any disease or condition so dangerous to life, it would have been heralded abroad, so that the profession throughout the world would be of one mind in regard to its value.

In those forms of extra-uterine development which allow the fœtus to live and grow to full term, or even beyond the fifth month, we would hardly be justified in destroying the fœtus and leaving nature to attempt to absorb so great a mass. A living fœtus beyond four and a half or five months had better be left to grow to a viable age and then be delivered by laparotomy, as Dr. Thomas has done successfully. The attachments to abdominal viscera would make it impossible to remove the ovum completely from its bed. Then, again, in cases where long development has gone on and the death of the fœtus occurs, we must be guided by the condition of the mother in our conduct of the case. Infection of the system would justify us in performing laparotomy to give the mother a chance by antiseptic treatment. In cases of rupture of the ovum in the early stages we should be prepared to operate, if necessary, to secure bleeding vessels and remove foreign substances from the peritoneal sac.

Dr. Cocks, in closing the discussion, observed that after a careful examination and he had made the diagnosis, he had written to Dr. Thomas, who advised an operation.

On the day of the operation the case seemed so urgent that rather than lose any time by going for his own galvanic battery, he had used a faradic battery that was in the house. This, he believed, held the patient over, so to speak, until he could procure and use the galvanic. This, he thought, could be done in the country, where it was difficult sometimes to get a galvanic battery at once, and would save time. He had used electrodes covered with cotton, and did not understand why there had been so much pain with both batteries used. The patient had a temperature of 101°, and that may have accounted for the pain. The number of cells used would have done as much harm as the vomiting from the ether.

It is said that the reason more physicians in France did not use the *Kochsalz infusion* as a treatment for cholera, was because they thought it had something to do with the discoverer of the cholera bacillus.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SIR ANDREW CLARK ON RELAPSING PNEUMONIA—A NEW TEACHING UNIVERSITY FOR LONDON—ARMY MEDICAL OFFICERS' PROMOTION EXAMINATION—SHOOTING FOR LUNATIC ASYLUMS—THE DEBATE ON CHARCOT'S DISEASE—THE BROWN INSTITUTION—MR. HORSLEY'S LECTURES—EXPERIMENTAL THYROIDECTOMY AND ITS RELATION TO MYXŒDEMA AND CRETINISM.

London, December 20, 1884.

Last Monday the Medical Society of London was again to the front. The event of the evening was the reading of a striking paper by Sir Andrew Clark on "A Case of Relapsing, or Intermitting Pneumonia, occurring in an Aged Man." The patient was a gentleman of active habits, aged eighty-two years. He had had an attack of pneumonia in 1877. He was first seen by Sir Andrew Clark in March last. He had then been unwell for five days, suffering from aching pains, feverishness, disordered digestion, and general feeling of malaise. On the day following that on which Sir Andrew first saw him he had a distinct rigor, and his temperature rose to 103°. The breath-sounds were feeble at the right base. A severe rigor occurred on each of the following days (March 27th and 28th) and the physical signs became more marked. On the 29th there was no rigor. There was then marked dulness at the right posterior base, increased vocal fremitus, and tubular breathing with broncophony. On the 30th there was general improvement, but on the 31st another rigor occurred, and the patient rapidly became ill again, the temperature, which had fallen to 100°, again rising to 103°. On April 2d the patient expressed himself as feeling well. His skin was moist, and there were moist crepitations over right base at back. Within a few hours the pulse and temperature again rose and there were signs of another relapse. Further consolidation was detected on examination. Cough set in for the first time and the face became bluish. He was again better on the 3d, but worse on the evening of April 5th, and severe rigors occurred on April 6th, 7th, 8th, 9th, and 10th respectively. Another occurred on the 13th. The patient was then much exhausted. He had a severe rigor on the 14th. The pulse was small and weak, and he had the appearance of a patient in the cold stage of cholera. He remained thus for four hours and then amendment set in. He improved from this date and was fully convalescent by May 6th. In the course of seven weeks he had passed through nine or ten severe rigors and six pneumonic consolidations, and this in spite of being under energetic treatment the whole time.

Sir Andrew Clark justly remarked that the case was one of great rarity. The question of whether pneumonia was really an inflammation or a specific fever was one which had occupied his mind for years. Dr. Sturges had maintained that it was inflammatory, and regarded it as the model of all inflammations. Sir Andrew said he had contested these views at the College of Physicians in 1866. In a consolidated pneumonic lung he failed to find any signs of cell-proliferation, and there were nothing but the signs of regressive change. The number of red disks extravasated in acute pneumonia equalled or exceeded the number of leucocytes; they underwent changes in the fibroid network, just as in blood-clots. In the alveolar septa there were no evidences of any changes except occlusion of some of the vessels. He believed pneumonic consolidation, though it might be an abortive inflammation, was much more like an active congestion in which capillary extravasation took place before the inflammation could be continued to its classical completion.

In the course of the discussion which followed, Dr.

Theodore Williams said he regarded acute croupous pneumonia as a case of blood-poisoning. He had seen similar cases, though the relapses were neither so frequent nor so severe. Dr. Rogers related the case of a gentleman seventy years of age, whom he was attending for rheumatic gout, and in whose family there was a history of gout, who had an attack of pneumonia with six relapses.

I have referred in a former letter to the movement for the formation of a new teaching University of London. Active steps have already been taken in furtherance of this object. A committee has been formed which already consists of over one hundred and sixty members, representing the existing teaching bodies, medical, legal, scientific, and others. An important meeting took place on Monday last, which was presided over by Lord Reay, Governor of Bombay. A lengthy report (drawn up by the sub-committee appointed in November) was read and adopted. It is determined first to approach the existing University with a view to obtain some modifications in its constitution and regulations. Should that prove impracticable the new body will, instead of coalescing with the older University, seek powers to confer degrees itself. The new scheme has a good prospect of being influentially supported both pecuniarily and otherwise.

The first examination for surgeon-majors in the army (previous to promotion) has just been held. A perusal of the questions certainly shows that the examination has been shorn of many of its anticipatory terrors, as they are all of an eminently practical character. The following are two out of the sixteen set: (6) What are the principal points to be attended to in the medical examination of recruits? (11) State how long you think a camp, whether of huts or tents, may be continuously occupied; why its sanitary condition should gradually deteriorate, and in what way this deterioration might be expected to manifest itself as regards the camp population?

The question as to the advisability of compelling army surgeons who have reached middle age to undergo an examination before they can be promoted to administrative rank is, of course, one still open to discussion.

Shooting is the latest amusement provided for insane patients. The renting of a moor for this purpose by a Scotch asylum has naturally excited considerable alarm. The fear is, very naturally, that the patients should literally "make game" of their keepers.

London, December 26, 1884.

The conclusion of the "Charcot" debate is far from satisfactory. A number of interesting facts have been brought forward, and some instructive cases and specimens shown. Professor Charcot sent over a valuable collection for exhibition, but failed to come over himself to take part in the discussion. It cannot, though, be said, that the recent interchange of opinion has done much to settle the subject. Many eminent authorities have spoken—some of them with no uncertain note—but there is as yet no prospect of any consensus of opinion amongst those who are qualified to express one. Perhaps the best description that can be given of our present standpoint is that embodied in Mr. Page's remark in the course of the discussion, that we are in a condition of "individual belief."

During the third evening devoted to the subject, Dr. Moxon, in proposing a vote of thanks to Professor Charcot, made a long speech, which was listened to with great interest, being most lively and interesting throughout. At the beginning of his speech he gave Sir James Paget a rap by saying he wished Sir James would make more clear what it was that he meant. Dr. Moxon expressed himself as being in accord with Mr. Hulke, and said he could see nothing peculiar in this so-called peculiar disease. He remarked that locomotor ataxy had branches, and he did not think Charcot's disease was a grafted branch. Westphal showed, eight years ago, that in general paralysis of the insane the conditions of locomotor ataxy were present. This statement drove him to St. Luke's, he said, but qualified his statement by explaining that he went "as an observer." He found Westphal's statement correct as regarded one-third of the general paralytics. The same was the case in Bethlehem Hospital, but in the latter no case of Charcot's disease had occurred among the general paralytics. Dr. Moxon said there might be some relation between this absence of joint-disease in paralytic and ataxic cases, and suggested that simple rheumatism might be changed into an exaggerated unrepresentative, irritative, severe, strange, and peculiar disease when occurring in cases of ataxia.

The Brown Lectures this year are of unusual interest. These lectures are delivered annually at the University of London under the terms of the Brown bequest. Mr. Brown was a wealthy gentleman who, by his will, left several thousand pounds for the purpose of founding a hospital for animals. The diseases of the animals were to be medicinally treated and also scientifically studied. Provision was also made for scientific experiments on animals. The institution was, under Mr. Brown's will, placed under the care of the University of London, the Senate of which was to be its governing body. A course of lectures was to be given annually in the University, open free to the public. (I may remark in passing that this is the sole attempt at teaching made by the University.) The first Superintendent was Dr. Sanderson and Dr. Klein was his assistant. The present Professor-Superintendent is Mr. Victor Horsley, M.B., B.S., London.

The first lecture this year was devoted to the subject of experimental thyroidectomy. Kocher has shown that, after removal of the thyroid, man becomes a cretin. Mr. Horsley has found that in monkeys a condition closely resembling myxœdema followed the operation. Several other symptoms also occurred. Muscular tremors came on in five days. Mucin was not a normal constitutent of the blood, but was present after removal of the thyroid. The salivary glands hypertrophied and secreted mucin. Dyspnœa came on but afterward disappeared. The larynx and recurrent laryngeal nerves were healthy.

Mr. Horsley said he came to the conclusion that the processes which occurred in myxœdema, cachexia, strumipriva, and cretinism were identical. He suggested that the thyroid gland consists of two distinct parts: one glandular, secreting mucin, the other lymphoid, and hæmatogenous in function. Excision of the gland was followed by profound blood changes, an increase in the amount of mucin in the tissues, increased activity of the muciparous glands, and the secretion of mucin by glands which usually yielded none, *e.g.*, the parotid. Nervous symptoms also occurred, viz., muscular tremors, rigidity and paresis, imbecility, and ultimately coma followed by death.

Mr. Horsley said he considered myxœdema and its allies was due to the loss—*actual or virtual*—of the thyroid. The removal of one lobe caused the other to enlarge, and if this were also removed, myxœdema followed. This favored the view of its being an excretory organ. Might it not excrete a mucinoid material injurious to the body, and that the loss of this excreting function caused death?

Two lectures were given on the thyroid. Two other lectures have been devoted to the subjects of traumatic and urethral fever respectively.

On Monday last Mr. Horsley gave at the Brown Institution an exposition of the methods adopted and the work carried on there. He also showed numerous pathological specimens prepared from the myxœdematous monkeys.

Young Physicians and Free Treatment.—The young physicians in the neighborhood of the dispensaries and college clinics are complaining bitterly against the managers of these institutions. It is asserted that patients abundantly able to pay are coaxed to accept advice gratis. The only excuse appears to be that the case will be interesting to the class.

OUR VIENNA LETTER.

(From our Special Correspondent.)

TUMOR OF THE BRAIN WITH REMARKABLE SYMPTOMS—AN ERROR OF DIAGNOSIS WITH FATAL RESULTS—ANTISEPSIS IN PROFESSOR BILLROTH'S CLINIC.

This week Professor Nothnagel reported in his clinic the following interesting case of brain disease: The patient, a man over sixty years of age, suddenly lost consciousness and fell in the street. Coma was profound. The attack was not preceded by any symptoms. Patient had been in good health to the date of the attack. There was also almost complete paralysis of the right half of the body. Recovery was rather rapid, but incomplete. He was able to walk with aid of a cane, and the intellectual powers were good. Several months after this loss of consciousness, patient had another apparently apoplectic attack and died. The autopsy showed a soft glioma the size of an orange, in the left hemisphere of the cerebrum. The most careful search showed no trace of a former or recent hemorrhage into the brain-substance or any other pathological condition. Professor Nothnagel said that the case was an extraordinary one, which he was not prepared to explain, especially the gradual recovery from the first attack. It showed that too great caution could not be exercised in making positive diagnosis in affections of the brain.

A somewhat remarkable case of diabetes is the following: Patient a male, forty-five years of age, coachman, in good health till two years ago, when he began to suffer with severe headaches in the occipital region, which continue to present time. Attacks of vertigo on sitting up or walking. Slight difficulty in the co-ordinative powers in walking. General muscular weakness, somewhat more marked on the left side. The left pupil slightly dilated and slowly responsive to light, also slight paralysis of the left vocal cord. Patient's general condition otherwise good. The patient passed at present 1,300 to 1,500 grammes of urine in twenty-four hours, and in the entire history of the case the quantity of urine per diem had never been over the normal amount. The specific gravity averaged for the past two months 1.014, and at no time had it been above 1.025. The particular specimen of urine exhibited with the case had a specific gravity of 1.010, and contained thirteen per cent. of sugar. This amount of sugar, or somewhat higher amount, had been found in the urine since the case had been under observation. Dr. Nothnagel considered the case as one of simple melituria and of great diagnostic value. Principally upon this symptom, taken with the others, he was able to make with great certainty as to the localization a diagnosis of tumor in the pons pressing upon the fourth ventricle. The case is also a very instructive one, as a case of sugar in the urine without polyuria, and what is more remarkable, with urine of a continual low specific gravity. Here is an instance of the value of the thoroughness of the German methods of examination before making a diagnosis. With such a low specific gravity the presence of sugar in the urine would certainly have been overlooked by an American physician, and thus an important aid in diagnosis, and a valuable symptom for treatment have been lost.

So common has gastrotomy become in Europe that at Professor Billroth's last operation of this nature, though it was announced beforehand in a crowded clinic, but few spectators, mostly foreigners, were present. The patient, a man of forty-two years of age, in apparently fair health, walked into the operating room unaided; he was fairly well nourished. Professor Billroth stated that it was a case of cicatrix from a simple ulcer of the stomach, which had contracted until it caused serious obstruction at the pyloric orifice, which would soon become complete, and he proposed to cut down upon the stomach, remove the cicatrized portion, and resect the pylorus. The abdominal wall was then laid open in the usual manner, and the stomach found to be adherent in various directions, in front and behind, to the surrounding tissues, and very much thickened with an abnormal growth. The duodenum was in a similar condition for several inches about its pyloric end. A diagnosis of infiltrated carcinoma was now made, an opening made in the anterior wall of the stomach, a similar opening made in the duodenum below the diseased portion, these two openings brought in apposition, and stomach and duodenum stitched together at the circumference of these openings, thus leaving free communication between stomach and intestinal tract. The abdomen was then carefully closed. The patient died from shock eight hours after the operation, and the autopsy at this writing had not yet been made.

Antisepsis in Professor Billroth's operations is most rigidly carried out. The bichloride of mercury solution has been tried, but not very thoroughly, and discarded. At present in the Billroth clinic are used carbolic acid in one per cent. and two and one-half per cent. solutions. Permanganate of potash, oxalic acid in weak solution, with always the use of soap and water in large quantities and repeatedly. The most scrupulous cleanliness with regard to instruments and the hands of the operator and all his assistants is insisted upon. Fresh wounds and all operative cases are always dressed immediately next to the skin with iodoform gauze. The results are striking; healing is almost invariably by first intention, and rarely does suppuration follow any of the operations in this clinic. In the other surgical clinics, and in the obstetrical and gynecological wards, a somewhat different method of antisepsis is followed. Everywhere, however, is iodoform used in large quantities. This is the iodoform era of antiseptics in Vienna. In a future letter I shall take occasion to describe more minutely the antiseptic precautions in use here, more especially those of the obstetrical and gynecological services.

CONCERNING THE SO-CALLED AMERICAN PLAN OF THE TREATMENT OF THE LATE LESIONS OF SYPHILIS BY LARGE DOSES OF IODIDE OF POTASSIUM.

To the Editor of The Medical Record.

Sir: Dr. E. C. Seguin, in an article in the *Archives of Medicine*, a bi-monthly journal, of which he is the editor, distinctly claimed the "method of giving the iodide of potassium in very large doses for the late lesions of syphilis" as an American method. He stated that "after considerable search, and by means of personal inquiries, I have satisfied myself that this plan is originally *American*, and that reliable tradition indicates that the promoter and prophet of it was the late Dr. William H. Van Buren." The article in question was made the subject of editorial comment in a recent issue of The Medical Record.

The claim that this plan of treatment was of American origin was not editorially considered. But in a subsequent number of The Record, November 22d, this was disputed by Dr. Crawcour, of New Orleans, and was claimed by him to be an English method, antedating the figures named by Dr. Seguin at least a year or two, Dr. Seguin having assumed on oral testimony that Dr. Van Buren was entitled to priority by prescribing it in this manner in 1861.

The asserted value of this treatment, as claimed by Dr. Seguin, and warmly supported by the editor of The Record, was fully appreciated and accepted by me. Being, however, personally cognizant of the fact that it was not originated by Dr. Van Buren in 1861, but had been well known, practised, and taught many years previously, I was satisfied that there was no good reason for claiming it as an American method. In order, therefore, to shield the medical profession in America from ridicule abroad, already foreshadowed by Dr. Crawcour's article, I wrote the article on the treatment of the late lesions of syphilis by large doses of the potassium iodide, which ap-

peared in THE RECORD of December 6, 1884. In this article I quoted from the case-book of Dr. William Kelly, Physician-in-Chief of the Charity Hospital on Blackwell's Island, cases of late lesions of syphilis, treated by drachm doses of the iodide of potassium in 1851, thus antedating Dr. Seguin's claims by ten years, and Dr. Crawcour's by eight. I also proved that this plan was publicly taught at that early period, by showing that Dr. Kelly was at that time the Lecturer on Venereal Diseases in the College of Physicians and Surgeons of New York. My own acquaintance with that plan of treatment was assumed to date from the time when, as I stated, I was an interne in Charity Hospital in 1851 and 1852, and might thus be presumed to be personally cognizant of the views and practices of Dr. Kelly in such cases.

Dr. Seguin replied to my article in THE RECORD of January 3, 1885. He opened by stating that "not having any personal interest in the question, I should be glad to be instructed and corrected; but I must say that Dr. Otis' letter quite fails to do the latter." He further says, "As regards Dr. Kelly's claim, it has some merit as a claim from private practice, but *there is no evidence that he exerted any influence upon his contemporaries or successors*, nor has any *printed* teaching of his been produced."[1]

Dr. Seguin based his claim for Dr. Van Buren's priority on the *oral statement* of Dr. William H. Draper, that in consultation with Dr. Van Buren in 1861, "the iodide of potassium was given in large doses (ninety grains a day to half a drachm every two hours)." And yet the written statement of Dr. Kelly, the Physician-in-Chief of the great venereal hospital of New York, taken from his own case-book, in which important cases in Charity Hospital were recorded at the time of their occurrence, is claimed by Dr. Seguin as not worthy of consideration. Dr. Kelly is shown to have been at that time the Lecturer on Venereal Diseases at the College of Physicians and Surgeons, and had a public clinic at Charity Hospital, and yet Dr. Seguin says, "*there is no evidence whatever that he exerted any influence upon his contemporaries or successors.*" And further he says, "*nor has any* printed teaching of his been produced."[1]

I confess that it is easier to produce Dr. Seguin's printed teaching than that of Dr. Kelly. I fail, however, to see that it is any more valuable than a similar statement made over his own signature.

If Dr. Seguin insists upon thus claiming, as valueless, all clinical and didactic teaching that has not found its way into print, he must retire from his claim of priority for Dr. Van Buren, and if Dr. Seguin's plan of dealing with prior well-authenticated written evidence is carried to its legitimate logical sequences he must retire also from the claim which he makes in his reply, that I have committed a "*slip of the pen*," in stating that I had taught the plan of treatment of the late lesions of syphilis by very large doses of the iodide of potassium in my clinic at the College of Physicians and Surgeons "for the past twenty-five years."

He says, "but the official records of the College show that Dr. Otis was placed in charge of the Clinic for Venereal Diseases in September, 1870, only fourteen years ago." I might thus, consistently with Dr. Seguin's position, claim that there was no evidence of the truth of the College records, because they had never been put into print, but I decline to take advantage of this. On the contrary, I admit the validity of the records. I must, however, also insist that the previous records of the College show that I was appointed Lecturer on Venereal Diseases in the College of Physicians and Surgeons in the spring of 1863, thus nearly twenty-three years ago.

It was my misfortune when writing the article in question not to have had the College records at my elbow. I did not make the statement referred to in order to establish any claim to priority in giving very large doses of the iodide of potassium for the late lesions of syphilis, nor in publicly teaching the same. (This credit I had already formally accorded, for America, to Dr. William Kelly, Physician-in-Chief to the Charity Hospital, New York, from 1848 to 1853.) I intended simply to show my own early appreciation of its value in my practice and in my teaching. I had shown that I was cognizant of the plan when I was an interne in Charity Hospital, in 1851. I was under the impression that I began to teach the subject of venereal diseases in the College of Physicians and Surgeons in 1860. It proves to have been in 1863. Assuming that in this early period of my life as a teacher, I had need of all the knowledge I then possessed on this subject, I naturally concluded that I did not neglect to make an early use of my knowledge on this important point. I am not even now able to state with certainty at what precise period I did begin to teach the plan of giving large doses of potassium iodide in syphilis. Having thus explained the grounds on which I made the statement in regard to the length of time I had taught the plan in question in the College, I wish now to say that all this is irrelevant to the questions at issue, viz.: First, as to the real originator of the plan of treating the late lesions of syphilis by administration of very large doses of the iodide of potassium. Second, as to the right and propriety of claiming it as an "American method." With the facts laid before the profession by me in THE RECORD of December 6th, and simply repeated in this article, I leave it to those interested, to decide as to whether or not we are entitled to claim the administration of very large doses of potassium iodide as an "American plan." My criticism in THE RECORD of December 6th was based solely on the previous *résumé* of Dr. Seguin's article, and Dr. Crawcour's letter in THE RECORD, and I had not then, as Dr. Seguin suggests, read his article. Having since done so with interest and profit, I found myself in complete accord with him in regard to the general excellence and efficacy of the plan. I have, in my previous article, expressed my views on the time and mode of administration of the drug, to which it is not necessary for me again to refer. I found that I had received an excellent *résumé* of the main features of the article from the editorial remarks in THE RECORD. Recalling Dr. Seguin's statement in his rejoinder, that "if Dr. Kelly *should be shown* to have been the originator of the method, my claim that it is an American method, is not shaken," I confess to considerable surprise when I observed in Dr. Seguin's original article a long quotation taken from Buzzard (page 120 of the *Archives of Medicine*), containing the following statement: "Forty years ago the late Dr. Elliotson used to give as much as ʒij. (8) three times a day and with remarkably good results." This referred to the potassium iodide in its relation to the late lesions of syphilis.

In view of a statement like this, I am unable to understand how Dr. Seguin could have laid claim to an American origin for the method of giving very large doses of the iodide of potassium in the treatment of the late lesions of syphilis.

The statement of Buzzard, if capable of substantiation, fully supports the claim of Dr. Crawcour as to the method being originally an English one; but Professor Ricord, has been shown by myself, in THE RECORD of December 6th, to have stated it as his practice to give the iodide of potassium under the circumstances in question as high as ninety grains a day. THE RECORD, in explanation of what constituted large doses of potassium iodide, stated them to be such as make up a total of from two and a half to ten grammes in twenty-four hours. I quoted Ricord as coming up to this standard. Dr. Seguin, however, shows that there was a misprint in THE RECORD, and it should have read drachms instead of grammes. Ricord gave ninety grains a day previous to 1835, and stated that he "had rarely gone beyond." This was over fifty years ago.

Dr. Kelly, formerly the Physician-in-Chief of the great

[1] Italics my own.—F. N. O.

venereal hospital of New York was claimed as an ardent disciple of Ricord, and is shown to have given the iodide of potassium in drachm doses (sixty grains) three times a day in 1851, thus thirty-four years ago, and made no mention of originality.

In summing up the whole matter, I think we must, in all fairness give whatever honor attaches to this valued discovery to M. Ricord, and admit that the increase in dosage was in no way entitled to be credited with originality. It was simply the natural and gradual outcome of subsequent experience with the plan originally taught by Ricord.

Very truly yours,

F. N. Otis.

103 West Thirty-Fourth Street, January 10, 1885.

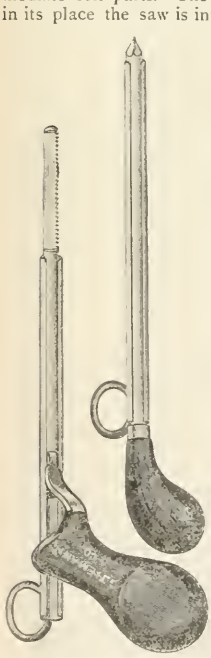
New Instruments.

THE SUBCUTANEOUS SAW AND KNIFE.

By GEORGE F. SHRADY, M.D.,

NEW YORK.

The subcutaneous saw, of which an illustration is herewith given, is believed to be an improvement on the one presented by me to the profession some time ago. The principle is essentially the same, but its application as compared with the former instrument much wider, and its construction much less complicated. It is now made in three parts: 1, a long, strong, blunt-pointed instrument, with limited saw-edge and fixed handle; 2, a trocar and handle; and 3, a canula or sheath open on one side throughout its entire length, and made to fit both saw and trocar. The trocar and canula are used as guides for the saw. They are first introduced to the bone to be divided by thrusting them through the skin and intermediate soft parts. The trocar is then withdrawn and in its place the saw is introduced, guided by the canula. The canula is in its turn withdrawn, leaving only the saw with its teeth in contact with the bone. The bayonet-bend of the saw near its handle allows the canula or sheath to slide back and forth over the saw-blade and past the deflected handle with the greatest ease. After the saw has done its work, and while it is still in the wound, the canula is slipped over its blade and the latter withdrawn in its turn. Finally, the canula itself is removed, leaving only the wound caused by the original track of trocar and canula.



By these means it will be seen that the introduction and withdrawal of the saw are effected without the possibility of any tearing of the soft parts by the teeth of the saw.

In many forms of subcutaneous osteotomy it will doubtless serve a useful purpose. In fact, the principle of construction of this instrument will adapt itself to any method of operation which demands the safe guidance of a saw or knife to deep, dangerous, or otherwise inaccessible points. In place of the saw, a knife or rasp blade can be used with the same ends in view.

The instrument is exceedingly simple in construction, easily kept clean, and not liable to break or get out of order. The figures represent respectively the trocar and canula ready for use, and the saw with the sheath in the act of withdrawal from the saw-blade.

The instrument has been constructed in a very satisfactory manner by Geo. Tiemann & Co., of this city.

Abortion Mistaken for Menorrhagia in a Woman aged Forty-two.—Dr. E. B. Ward, of Greensboro, Ala., writes: "A multipara, aged forty-two, had been flowing continuously for over seven weeks. She did not know that she was pregnant, and was treated for menorrhagia by another physician." Dr. Ward was finally called in just in time to find a fœtus and membranes of about two and a half months which had been expelled in toto. The patient recovered.

DISEASES OF THE FALLOPIAN TUBES.[1]

BY W. GILL WYLIE, M.D.,

PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC; GYNECOLOGIST TO BELLEVUE HOSPITAL, NEW YORK, ETC.

IN looking up the literature of salpingitis, minute descriptions of the pathological anatomy will be found in the writings of Kiwisch, Förster, Rokitansky, and later Martin Klob, Schroder, Henning, and other German writers; but little advance was made in the treatment until a few years ago, when Mr. Lawson Tait made known his wonderful success in removing diseased tubes. The writings of Battey and Hegar on removal of ovaries also had an influence in developing the proper plan of treating diseases of the uterine appendages.[2]

Dr. J. Marion Sims, for several years before his death, was much interested in the subject, and, as his assistant, I helped him in a number of cases. But it was not until I was appointed one of the gynecologists to Bellevue Hospital and began my clinics at the New York Polyclinic, in 1882, that I had an opportunity to study clinically a large number of cases. Since then I have made a careful study of the subject, and since May, 1883, when I did my first operation for removal of diseased tubes, I have operated upon fourteen cases for diseased uterine appendages, not including operations for ovarian or uterine tumors. Each of the fourteen cases were under my observation and treatment several weeks before the operation, and many had been kept in my ward at Bellevue three, six, and one or two even nine months beforehand. By a careful study of each case and by the use of preparatory treatment to soften and relax the adhesions, I was able, in almost every case, to make a more or less exact diagnosis before operating. Of these, nine were operated upon in either the Sturges or the Marquand pavilion at Bellevue Hospital, the remaining five were in private practice. Twelve recovered and two died of septicæmia on the fifth day; the latter were hospital cases. Eight were cases of pyo-salpinx; two hydro-salpinx, and four catarrhal tubes with peritoneal adhesions. With one or two exceptions, there were extensive adhesions from local peritonitis and the ovaries were either diseased or more or less covered with adhesions, and, in three instances, abscesses were found involving the extremities of the tubes and the ovaries. Short histories of each case were read, and twelve of the fourteen specimens, with a report on the specimens by Dr. H. C. Coe, Pathologist to the Woman's Hospital of the State of New York, were shown last night at the New York Pathological Society. Many other cases were kept under observation and clearly diagnosed, but either because the patients objected to the operation, or the subjective symptoms did not justify it, they were not operated upon.

I am satisfied that a careful study of the diseases of the Fallopian tubes will not only clear up most of those numerous and once incurable cases of local peritonitis (in this country commonly called cellulitis), but also most of the cases of retroversion, retroflexion, and lateral flexions with adhesions, and that their proper treatment will make plain the uselessness and danger of using pessaries in such cases. I do not mean to say that every case of local peritonitis will be found due to salpingitis, but that, in the large majority of cases, salpingitis precedes the local peritonitis, and that repeated attacks of local peritonitis are, as a rule, caused by salpingitis.

In my opinion when the frequency and the great importance of diseases of the Fallopian tubes is generally understood, the fascinating teaching of the mechanical pathologist, namely, that most of the ills of women are due to uterine displacements, that the real disease is the version or flexion, and when this is corrected and the uterus is held by a pessary in an ideal normal position that all will be well, will fade to small proportions and the relatively few lines now to be found in our text-books on salpingitis will increase rapidly, and there will not be so many hundred pages on cellulitis, displacements, and pessaries.

Etiology.—Anything which causes endometritis may induce disease of the Fallopian tubes, and it is probable that in most cases salpingitis is due to an extension of disease from the lining membrane of the uterus directly to that of the tubes. In virgins it is comparatively rare, except from catarrhal disease. In imperfectly developed and delicate girls and women, the degenerate state of the mucous lining makes it an easy prey to catarrhal disease, and an endometritis may be extended to the tubes. Tubercular disease may also attack the Fallopian tubes.

Many of the profession, especially those who treat genito-urinary disease in the male, look upon gonorrhœa in women as a very trivial disease, probably because it does not produce urethral strictures. When Dr. Noeggerath read a paper on this subject before the American Gynecological Society, in 1876, his views on gonorrhœa may have been extreme, but on salpingitis they were well in advance of the general knowledge on this subject at that time, and now, if the gonococci causes the disease and he can find the gonococci in all, or in most of his cases of latent gonorrhœa, his theory will be proven to be true. There is no doubt but that gonorrhœa is a very frequent and in many instances an unsuspected cause of salpingitis. Among prostitutes this disease and septic endometritis following abortions, by causing salpingitis, accounts for the incurable sterility so universal among this class, even though they return to the paths of virtue. Early in its course, before the poison has reached the deep-seated glands of the vagina, or the lining membrane of the uterus, it may be checked in its course by repeated applications of a solution of a mercuric bichloride or some other antiseptic, but when once it enters the uterus it cannot safely be treated locally until it has become subacute, for any attempt to introduce even a small probe may cause uterine contractions and pains which are pretty certain to be followed by local peritonitis within the next twenty-four hours, and the probability is, that this is caused by the tube becoming infected by the contractions forcing the poison in from the uterus. Even when treated with the greatest care, specific endometritis will in many instances cause salpingitis and local peritonitis. I have selected several well-marked cases and put them to bed, and watched the course of the disease from the vagina to the uterus, from the uterus to the tube and peritoneum. Salpingitis from gonorrhœa may result in active pyo-salpinx with a thick yellowish or greenish pus, or it may

[1] Read before the New York Academy of Medicine, January 15, 1885.

[2] The author does not desire to discuss the claims of Tait, Battey, and Hegar, but there can be little question that, among the English speaking profession, Battey first made plain that we should operate upon certain forms of ovarian trouble besides ovarian tumors, and Lawson Tait first taught us that we should and could remove diseased Fallopian tubes in many cases. Hegar may have done the same thing in Germany.

become chronic and the discharge gleety and thin in character. The tubes may close at the fimbriated extremity, and after the first attack of local peritonitis drain into the uterus, but frequently after a time the tube becomes distended on account of a stricture of the proximal end, and the patient may have repeated attacks of local peritonitis, indicating that the adhesions which nearly always seal up the fimbriated extremity have yielded or the poison in some way has reached the surrounding tissues.

Syphilis may cause salpingitis, just as it does otitis or ozæna. Some of the most obstinate cases of endometritis that I have ever seen have been in syphilitic subjects.

Septic poisonings after labor and abortions, especially after the latter, is a frequent cause of salpingitis. After abortions the cervix uteri is not so patulous as after full term labor, the cervix being more irritable and likely to contract and obstruct drainage, and any effete matter may be not only retained in the cavity of the uterus, but when the uterus contracts it may be forced into the Fallopian tubes.

It may be a disease that induces the abortion, and this extends to the tubes. Besides, after an abortion, neither the patient nor the doctor are as likely to keep up the usual precautions and give time for involution to take place. Sub-involution and endometritis are much more common after abortions than after normal labor. It is my opinion that in most instances it is through the tubes that septic poison causes local peritonitis. Septic material is, of course, often absorbed directly from the uterine tissues by the blood-vessels and lymphatics, but the poison is carried into the circulation, and does not directly enter the peritoneal cavity. Local peritonitis is much more common on the posterior surface of the broad ligament than on the anterior surface, for the tube opens on the posterior surface of the broad ligament. My experience leads me to attach much more importance to local peritonitis than local cellulitis, for, except after septicæmia, where the poison has become localized in the cellular tissue, producing a phlegmon, the cellular tissue is, as a rule, merely affected by contiguity with the inflamed peritoneal tissue, and I do not believe in so-called "chronic cellulitis." Hydro-salpinx may be due to other causes than venereal or catarrhal disease, but in what way it has not been made clear to me, although I must admit that I have seen some cases not satisfactorily explained by saying that it is the sequel of catarrhal disease or subacute inflammation. Small thin cysts may be found on the outside of the tube, but these more properly belong to the broad ligament. Diseased tubes are very commonly associated with diseased ovaries, and I think in most instances the disease of the tubes precedes that of the ovaries, and the diseased ovaries are but the result of an extension of the disease from the tubes to the ovaries and peritoneum. But certain diseases of the ovaries may cause disease of the tubes, such as cancer.

In several cases I have found cystic disease of the ovaries associated with catarrhal disease of the tubes, and it is this combination which I have noticed in the worst cases of hystero-epilepsy. In fact, if I have a well marked case of hystero-epilepsy or hysterical patient to operate upon, I expect to find cystic or atrophied ovaries with catarrhal disease of the tubes.

Hemorrhages into the tube may result in more or less permanent distention, and anything which stops up or diminishes the size of the lumen of the tube may obstruct drainage and result in disease and distention.

Symptoms and diagnosis.—The subjective symptoms are very variable. A peculiar burning pain over the seat of the tube affected is, perhaps, more characteristic than any other symptom, but many patients have no such pain, and local sensitiveness and a dull pain over the tubes and ovaries is about the only constant symptom; sometimes a dragging pain or sensation will be present when the patient stands, or there will be backache and headache, such as is supposed to be due to displacement, which are so commonly associated with, and are often due to the diseased tubes.

Dysmenorrhœa is a common symptom in these cases, but in some the flow gives relief by lessening the congestion, and I am inclined to believe that the pain is often caused by the endometritis, or the result of the endometritis in producing contraction and hyperæsthesia of the mucous membrane, for in those cases where all stenosis and endometritis is cured by treatment, as a rule, the dismenorrhœa disappears. Menorrhagia or metrorrhagia is often associated with salpingitis, but I think it will most frequently be found to be due to vascular changes in the lining membrane of the uterus, and a thorough curetting with a good instrument may effect a cure, although great care must be exercised in preparing the case for operation lest the salpingitis be so disturbed as to start up peritonitis.

Sterility is the rule in salpingitis, and when both tubes are affected, which is usually the case, it is incurable, but when only one side is affected and the proximal end of the tube of the diseased side is closed, pregnancy is possible and may go to full term, but as the uterus enlarges there may be severe local pain, and abortion is likely to occur.

Perhaps the most reliable indication of severe salpingitis is the occurrence of repeated attacks of local peritonitis, or active pelvic congestion without other evident good reasons for such attacks. Wet feet and exposure to cold may be an exciting cause and induce a catarrhal attack, and thus bring on endometritis, etc., but when exposure is followed by peritonitis, I would always look for a latent salpingitis or some such real cause.

Objective symptoms.—In acute cases there is usually so much swelling and tenderness that about all we can make out is a fulness or thickening of one or both broad ligaments, associated with more or less fixation of the uterus. Take such a case and keep her in bed until the painful symptoms completely subside. Then place thin pledgets of cotton saturated in pure glycerine against the cervix uteri two or three times a week, and, as the case becomes subacute, add alum to the glycerine and continue the pledgets for from three to eight weeks, and the inflammatory products will be so much absorbed or stretched that the uterus will become movable, and an expert may be able to define an enlarged tube or a mass that he can make out to contain a diseased tube or ovary more or less prolapsed and adherent in one or both broad ligaments. In subacute cases a diagnosis may be more easily made, but often a doubtful case can be cleared up by the same treatment recommended for acute cases. A diagnosis is especially easy when only one side is affected and the uterus is not retroverted. By the prolonged use of pledgets of cotton, soaked in a mixture of alum and glycerine, a distended tube can be readily defined by bimanual examination. Of course much will depend upon the thinness and laxity of the abdominal walls, and now and then a case will be found that, to get a clear diagnosis, it is necessary to examine the patient under ether. In some cases the floor of the pelvis is so fixed by adhesions, and there is so much venous congestion or enlargement of the pampiniform plexus, especially of the left side, that a certain diagnosis cannot be made; a prolapsus of, or adhesions to the sigmoid flexure may complicate and make a diagnosis more difficult. In some cases of catarrhal tubes they are not distended, but feel like a thin band of adhesions. The ovaries are apt to be more or less cystic, or are often infiltrated and enlarged by inflammatory products, and are nearly always prolapsed with and folded under the tubes on either side.

Sometimes, when the proximal end of the tube is patulous, the discharge will enter the uterus, and I have seen one or two cases where, from an accurate knowledge of the state of the uterus and vagina, it could be made plain that the gleety discharge has come from the distended tube; after cleaning the vagina and uterus, fresh

pus could be made to appear in the vagina by slowly pressing upon the distended tube. The fluid may escape intermittently into the uterus, and, if irritating, may set up each time an acute endometritis. Now and then a tube distended with fluid will empty a large amount of fluid into the uterus at once, which, for the time, flows freely from the vagina, and the tube will refill and again discharge.

Pathology.—In the literature of salpingitis comparatively little is to be found in English on the subject, and until very recently it was hardly mentioned in our text-books. We are compelled to go to German writers, where, as before mentioned, we will find full and accurate accounts of the pathology. I will not attempt here to give the microscopical appearances, but to bring out more especially what may be called the surgical pathology. As has been before stated, salpingitis is nearly always caused by the extension of disease from the endometrium to the lining membrane of the tubes. Now, aside from the different character of the mucous membrane of the uterus from that lining the tube, the different shape, size, and position of the tubes from that of the uterus also makes a marked change in the results of the same disease.

Inflammation of the endometrium causing enlargement of the uterus may result in displacement, imperfect drainage and parametritis, but this is not the rule; besides, the uterus is accessible and directly amenable to local treatment, while inflammation of the lining membrane of the tube which causes swelling is almost certain to result in prolapse of the tube and obstruction of the naturally small lumen, and thus cause imperfect drainage, and almost always induces peri-salpingitis on account of the open extremity emptying its contents into the peritoneal cavity. The tube cannot be directly treated; the lumen cannot be dilated, and perfect drainage secured as in endometritis. Hence salpingitis nearly always becomes chronic, in many instances lasting as long as the patient.

The first effect of disease reaching a tube, is to cause it to become engorged with blood; as it is loosely attached to the upper border of the broad ligament, it sinks lower in the pelvis covering or folding over the ovary, and as the beginning of salpingitis, after labor or an abortion, is so often associated with an enlarged uterus, this organ sinks lower, and as the patient during the acute stage is, as a rule, on her back, the fundus inclines backward. Now, suppose the uterus is enlarged, lying backward, and the disease affecting the uterus extends to the tubes, they swell, sag backward and downward, covering the ovaries, and as soon as the discharge or the disease reaches the peritoneum through the open end of the tube the peritoneum becomes inflamed, lymph is thrown out, gluing the different organs together. As the acute stage subsides, the lymph contracts, bands of adhesion draw and distort the organs, and the folded, twisted, and adherent broad ligament holds the uterus in its backward displacement. As a rule, the peritoneal tissue covering the fundus is not adherent to the tissues behind the uterus, although this seems to be the case when an examination per vaginam is made. The uterus may sink lower, being drawn down by contraction of the adhesions, and it may become retroflexed when the adhesions are extensive and the contraction great. Again, the tube being smaller and displaced, the lumen is stopped, the discharge accumulates, distends, and leaks into the peritoneal cavity, a fresh attack of peritonitis sets in, more lymph is exuded, and as the acute stage subsides the tubes and broad ligaments are rolled back and folded in more and more; as the contraction goes on, the tissues harden and the tubes may form strong cords, which, being adherent to the floor of the pelvis, fix the uterus in its retroflexed and retroverted position. Thus we have cases of retroversion with adhesions, and it is the rolled up ligaments and the tubes which fix the uterus backward; and it is the imbedded ovary and diseased tube in the hardened tissues of the broad ligament which makes it next to impossible to insert a pessary and hold the uterus up without causing pain and running the risk of bursting or tearing a tube distended with septic or irritating fluid. By great patience and time, in many cases we can stretch the ligaments, and by force get the fundus uteri into that ideal normal position, but to keep it there is the rub; the rolled up broad ligaments won't unroll, and when put on the stretch by the uterus being held up by force, they soon begin to ache, inflame, and may cause local peritonitis.

Now suppose only one tube is affected, the retroversion will be less, and if the other side is not affected the uterus may be even a little anteverted, unless the inflamed tube drops to the floor of the pelvis. If the ovary and the tube of the affected side are prolapsed and inflamed, as contraction takes place the broad ligament is shortened, especially on its lower side, and unless the tube and ovary are very much distended, so as to displace the uterus bodily, the cervix is drawn to the affected side, the fundus being tipped toward the healthy or less affected side, which is usually the right side, and the swollen ovary and tube may be forced backward somewhat behind the uterus. When one side only is affected, it is usually the left; the circulation on this side, from the formation of the veins and the proximity of the often-distended intestine to the left broad ligament, seems to make it more susceptible to congestion, prolapses, and disease than the right side. When both tubes are involved, the left is probably the first to become affected, this, together with the natural position of the uterus being that with the fundus inclining slightly to the right of the centre, accounts for the fact that where both tubes are affected and the uterus is not retroverted, the cervix is drawn to the left and the fundus to the right, the left ovary and tube being prolapsed, and the right usually much less prolapsed. In nulliparous women, especially in those cases where the uterus is anteverted or anteflexed, and where the disease is gradual in its progress, this condition of right lateral flexion with the fundus forward is most likely to be found, whereas, after labor and abortions salpingitis is more frequently associated with retroversion. Sometimes the prolapsed tube, especially on the left side, is adherent to the sigmoid flexure or to the small intestine, and the omentum may have slipped down, especially when the uterus is retroverted, and become adherent over and in front of all the pelvic organs, when it has been thickened and the blood-vessels greatly enlarged by repeated attacks of local peritonitis or general peritonitis. To the inexperienced it is a formidable barrier; years ago I saw even Dr. Sims close the abdomen rather than run the risk of going through it to reach the ovaries beneath it. These are the cases where eminent men will tell you that they opened the abdomen, but could not find the ovaries and tubes, therefore closed it. When describing the operation, I think I can make it plain that by a simple procedure this apron of blood-vessels can be safely removed. It has enabled me to complete the operation of removal in even the worst cases. Where the local peritonitis is limited, as the tubes open near the ovaries which protrude through the posterior surface, the adhesions are, as a rule, confined to the posterior layer of the broad ligament, this accounts for the rarity with which the bladder is affected by the adhesions. The ureters are not uncommonly affected by the adhesions, especially when the adhesions are low on the floor of the pelvis, and in tearing up very old and firm adhesions the ureter may be lifted up (on one occasion it would have been tied had I not recognized it as it was lifted up by the operator).

Now, as to the tubes themselves, in cases of simple catarrh, especially those associated with cystic ovaries—a combination which seems to be the most certain to produce hystero-epilepsy, hysteria, and all kinds of reflex disturbances—the tubes may be very little enlarged, but very vascular and adherent, with the lining membrane in

a mild catarrhal state. Later in the disease, more commonly the tube is distended by fluid and enlarged from the size of a lead-pencil to enormous dimensions, with the fimbriæ turned in and the end of the tube closed, or the fimbriæ may be spread out and adherent to the surface of the ovary, the latter acting as a plug to the mouth of the tube. The end of the distended tube may be adherent to the side of the pelvis, or the floor of the pelvis, to an intestine, or even to the other tube. The distended tube may be, and when large is, more or less convoluted, sometimes constricted at one or more parts, and usually with the outer end much larger than the proximal end. The fluid distending the tube may be clear, transparent, watery fluid, or milky or gleety, or thick greenish colored pus, or thin broken down pus. Ciliated epithelium is the chief microscopical characteristic of the clear fluids. When the tube is greatly distended and the adhesions slight, it is usually a hydro-salpinx, but when large with many adhesions it is likely to be pus that distends the tube. In my cases, in the majority of instances the tubes were infiltrated with pus and serum, and degenerated rather than distended. In those where abscesses were found formed in the substance of the ovaries and tubes, the tissues were so rotten that in tying them off the ligatures cut through the degenerated stump, and I was compelled to pick up the arteries and tie them one by one. These might fairly be called cases of pelvic abscesses. In old cases the tissues may have atrophied and contracted down so that it is difficult to remove all of the ovary and have a stump long enough to hold the ligature. In most cases the ovaries are covered with the inflamed tube and shreds of adhesions, and in pyo-salpinx they may be inflamed and filled with small abscesses or infiltrated with pus, and are sometimes so degenerated that they are torn to pieces in being removed. Sometimes the interstitial tissue of the ovary is affected, and may be hardened and contracted, or the ovary may be found abnormally small and atrophied, but the most common condition of the ovaries, if affected by an independent disease at all, is that of cystic degeneration; usually the cysts are numerous—small ones filled with a gummy, translucent fluid. Superficial cysts with thin fluid are very commonly found, but deep-seated central cysts may fairly be called cystic degeneration, and it is to this class I refer when speaking of cystic degeneration of the ovaries.

In some cases, the cellular tissue may be infiltrated and thickened by lymph, but the preparatory treatment almost always, more or less, completely removes this lymph, and the real adhesions that bind and twist the organs out of place will be found to be peritoneal.

Prevention.—When the etiology of any disease is well understood the prevention is plainly indicated. It is important that the general health and strength of girls while developing into women should be kept up, so that the generative organs will fully develop and resist catarrhal disease. When there are symptoms of catarrhal disease, such as leucorrhœa and dysmenorrhœa they should be treated early, before it has reached the Fallopian tubes, and if the endometrium is affected by disease the uterine canal should be kept patulous so as secure perfect drainage, and thus lessen the chance of the disease entering the Fallopian tubes. The serious nature and the almost certain consequences of venereal diseases should be explained to and impressed upon all young persons, and definite instructions should be given, especially to all male patients suffering with gonorrhœa, to avoid intercourse until complete cure is affected. No doubt many of the cases supposed to be due to septic poisons after labor are really caused by gonorrhœa contracted from husbands who have been led astray while deprived of their usual indulgence during the confinement of their wives. The serious consequences of even a slight septic endometritis in causing a salpingitis makes more forcible the great importance of cleanliness and the use of antiseptics or any other means that may lessen the chance of puerperal septicæmia. We know that subinvolution rarely exists without, sooner or later, the development of endometritis, and instead of taking it for granted that when a woman has passed the ninth day after labor that the doctor's responsibility in the case is at an end, every lying-in woman should be examined locally before she is allowed to go about her usual duties, and it is safer to keep the woman under observation until the uterus is normal in size, position, and condition, before dismissing her. If treatment is needed, it is better to begin it not later than the end of the second week after labor. A few stimulating applications of glycerine and alum made twice a week during the third, fourth, fifth, and sixth week after labor will prevent subinvolution, retroversion, endometritis, and a salpingitis in a delicate or weak woman that without it would be pretty certain to be affected with one or more of these serious affections.

When we have an endometritis it is especially important that we should secure perfect drainage from the uterus. After abortions the greatest care should be taken to prevent septic infection and insure removal of all the placenta and membranes. Especial care should be taken to secure perfect involution and drainage of the uterus, for after labor nature generally accomplishes this without help, but not so in abortions. Labor is normal, but abortions are abnormal, and must be regarded as almost certain to result in disease.

Treatment.—During the acute stage complete rest in bed is the best treatment; anodynes and counter-irritants may be used; as the active symptoms subside, I begin the application of thin pledgets of cotton saturated in pure glycerine and applied to the cervix and vagina; they are left in place twenty-four hours, then removed and a douche of hot water given; on the third day another pledget is put in, and this is kept up for a week or two; and later a solution of one part of boro-glyceride, one of alum, and fourteen of pure glycerine is used to saturate the cotton in place of pure glycerine. After a week or so this softens out the products of inflammation and renders the uterus more movable, and enables one to make a more accurate diagnosis. It improves the circulation, and often gives, for the time, more or less complete relief to all the local symptoms. While this simple local treatment is given, close attention should be paid to the general health, and the condition of digestion, and especially the bowels, should be carefully regulated, for impacted fecal matter in the lower end of the descending colon or rectum may materially add to the pain and the effects of the disease by pressing directly on the left broad ligament.

After getting the uterus movable, so that it can be pulled pretty well down with the tenaculum without causing much pain, it will be safe to sound the uterus, and, if the canal is contracted and hyperæsthetic, it should be gently dilated so as to secure good drainage and enable applications to be made to the mucous lining. If there is a history of excessive hemorrhage, and it is not corrected by tincture cannabis indica, twenty gtts. given twice a day, if the uterus can be gotten movable by the use of the medicated pledgets, it will be safe to curette the uterus for the removal of granulations. I would always give the above treatment as preparatory to operation, except in those cases where the diagnosis was plain and indicated immediate action to prevent rupture of a painful cyst, or to prevent septic poison and death after rupture. In these cases I would resort at once to the operation for removal. Aspiration through either the abdominal wall or vagina can give only temporary relief by evacuating the contents of a cystic tube or ovary, but there is some risk and little or no permanent good attained. Where a large amount of pus had accumulated in three cases, and abdominal section would not be permitted, I have resorted to a simple method of opening and draining. With a long and curved trocar I punctured the walls of the abscess, being careful to pass the trocar directly behind the cervix so as to avoid large blood-vessels and the ureters. After passing the trocar the canula

was withdrawn and the pus evacuated, and the cavity repeatedly washed out with solution 1 to 5,000 mrc. bichl. With canula still in place, I turned patient on her side in Sims' position, and introduced Sims' speculum in the vagina; then I passed through the canula a small probe without a handle, and slipped the canula out over the probe, using the probe as a guide; with Sims' uterine dilator I dilated the opening so that I could pass my finger into the abscess. By means of a pair of slender forceps I carried into the abscess a large-sized drainage tube of soft rubber; in this way I avoided the use of a knife and the risk of cutting a blood-vessel or the ureter. To prevent the tube from slipping or being forced out as the cavity of the abscess contracts I passed a silver suture through the posterior lip of the cervix and the wall of the drainage-tube and tied the tube to the cervix. The cavity was washed out with an antiseptic solution as was indicated by the discharge and temperature of the patient; as the discharge diminished, the large tube was replaced by a smaller one, and the opening kept dilated until all drainage ceased.

One of the three cases seemed to be permanently cured and all were helped, but I would not advise this treatment, except in those cases where abdominal section is not allowed, or where there seems to be only one large cyst, such as is sometimes found following a broken-down hæmatocele. In most cases the abscess or distended tube is too small to be reached safely in this way. If, after opening the abdomen and finding a large pus cavity, I wished to make a counter-opening through the vagina, I would make a small opening with a trocar and then dilate it with dilators. In case of a large pelvic abscess pointing toward Poupart's ligament, I would open by an incision in the groin and would not enter the peritoneal cavity above the abscess, except to secure complete removal or to get perfect drainage.

When diseased tubes are plainly made out and the patient is bedridden, or suffers to such an extent that after being clearly informed as to the effect and danger of the operation and consents, then we consider complete removal of both tubes and ovaries, if both sides are affected, to be justifiable. By softening the indurated tissue and improving the circulation of the pelvis we can help but not cure. By atrophy and absorption nature may cure, but chronic invalidism usually comes before nature has effected a cure. Or, by the bursting of a distended tube, general peritonitis and death may follow instead of the usual attack of local peritonitis. Many a case of so-called idiopathic peritonitis has been caused by the bursting of a diseased Fallopian tube, and the patient might have been saved by a bold surgeon even after the peritonitis set in.

Operation for removal.—I do not expect to improve upon Mr. Tait's work as an operator, but I think I can make the operation easier to others by describing a methodical way of doing the operation for removal of the tubes and ovaries, in cases where the adhesions are extensive.

After giving the preparatory treatment with glycerine and alum pledgets as described, and having decided that an operation is proper, I have the patient's bowels well emptied and put her on pancreatized milk diet with very little other plain food for three or four days previous to the operation, the object being to remove all impacted fecal matter, and to lessen the amount of gas in the intestines, for the latter may be very troublesome by crowding down around the pelvic organs and out through the incision in the abdominal wall during the operation. When well prepared, there will be little or no gas in the intestines, and they will be found to be like so many slippery ribbons. The day of the operation the bowels should be well moved, but not excessively.

In all surgical practice I would place cleanliness first, drainage second, rest third, and antiseptics fourth. If we could be perfect in cleanliness, antiseptics would be useless. Some of us are willing to be considered fallible and use antiseptics to make up for it. Before Lister made perfectly plain the necessity of cleanliness and proved the value of antiseptics, not many of us were so particular about cleanliness, nor did we know how important it was to success in surgery. Cleanliness is better than antiseptics, just as prevention is better than cure. Before Lister's teachings, what surgeon spent hours in cleaning instruments and sponges, and placed over wounds a thick layer of absorbent cotton-wool? Cotton-wool is known to be the best thing to prevent the passage of germs and their spores, and he who uses it for dressing wounds carries out the principles taught by Lister.

Before operating, my patient is thoroughly bathed and clean clothing for her body and bed ordered; just before being etherized, one quarter to one-third of a grain of morphine is given hypodermically. When under ether, the abdomen is shaved well down to the pubic bone, and thoroughly washed with soap and water, and before the skin is cut, again well washed with a solution of one to five thousand of mercuric bichloride. Instruments are all kept in solutions of one to twenty No. 1 Calvert's acid. carbol., and sponges in a solution of one to ten thousand of mercuric bichloride. Besides the operator, only four assistants are needed: one to give ether, one to handle instruments, one to clean sponges, and one to stand opposite the operator and sponge. Ordinarily the man to hand instruments can be dispensed with, and I do not use any one for this purpose except in my hospital clinics, for of course the number of persons helping adds to the danger of infection. All assistants are required to wash as clean as possible, and use solution of bichloride afterward.

In putting the patient on the operating table, I place a soft pillow under the shoulders and one under the head, and have the feet so fixed as to keep the knees about level with the abdomen. This relaxes the abdominal wall to some extent. The bladder is emptied, and the abdominal incision is made just above the pubes. The length of incision in the skin being from two and one-half to three inches, according to the amount of fat in the abdominal walls, the opening in the peritoneum being only large enough to allow the free use of my index and middle fingers at the same time. This opening is rarely made larger, unless the size of the distended tube or ovary makes it absolutely necessary in extracting them. A larger opening is avoided, because it adds to the risk of septic poisoning, and makes ventral hernia more likely to follow. When ovarian and other large tumors are removed, the abdominal walls are relaxed, and there is less tension on the sutures and perfect union is more readily secured than in those cases where the abdominal pressure is normal.

When the subperitoneal fat is reached, it may be troublesome to get through it, for there is no distended tumor directly underneath it to keep away intestines and hold the many layers of the peritoneum together, and where gas is in the intestines this difficulty is increased. Where the omentum is free from adhesion, it can be pushed up as one would the end of an apron. When it is adherent, as it often is, to the broad ligament and anterior wall or top of the uterus, it cannot easily be separated by pulling it from below upwards, but by passing the two fingers well to one side and getting them underneath, and separating the adhesions, many formidable looking cases can be easily managed. As the adhesions separate, they should be lifted through the opening and any bleeding points tied. The principal vessels in adhesions of the omentum come from those of the omentum, and not from the pelvic organ; therefore, the end of the omentum is the part to be tied. If the adhesions are strong and vascular, as they may be in those cases where there have been repeated attacks of local peritonitis, then the omental adhesion can be tied off, tied first as low as possible, and then a little above this, and cut between the ligatures. By pulling the sides of the abdominal opening laterally with

retractors, we can do this without enlarging the opening in most cases. In handling and tying the omentum, care should be taken not to split or tear it, for it will invariably bleed up in the angle of the split, and may be very troublesome. Where the uterus is retroverted, the removal of the omentum, as a rule, frees the anterior part of the fundus and the anterior face of the broad ligaments; often the small intestines will have to be separated, but are not often firmly adherent. The next step is to elevate the uterus by placing the fingers behind it. The back of the fundus may be adherent, but, as a rule, it is free and is held back by the twisted and rolled up state of the broad ligaments. The ovary will be found folded under the tube and broad ligament, and to get it up we must go down through the broad ligament, or we must unroll the broad ligament. I have seen the former done several times, and it always adds greatly to the length of the operation, and necessitates tearing or tying off the outer attachments of the broad ligament before the tube can be gotten up and tied off with the ovary. Now, by putting both fingers directly down behind the uterus, and running the fingers laterally, guided by the Fallopian tubes, as it is given off from the uterus, and gradually separating the adhesions and unrolling till we get under the ovary, the tube and ovary can be gotten up easily in the worst cases; where the adhesions are very firm, an assistant's finger in the vagina as a guide may be useful, for in scratching loose the adhesions the ureter may be lifted up, and the sigmoid flexure or rectum may be torn up, for it may be adherent to the tube or ovary on the left side. When both sides are adherent it may be well to lift up both sides before tying either; although in some cases, where the bleeding is free, it may be better to tie the first one lifted up. In three cases I found the tissues so degenerated that my ligature cut through, and compelled me to slightly enlarge the abdominal opening and tie the arteries after picking them up with a bull-dog forceps. Where the tissues are frail and ligatures inclined to cut easily, it is safer to remove the tissues and tie the arteries separately. Two or three arteries will usually be found. Where the broad ligament is much enlarged, we may tie with two ligatures, one double ligature including the ovarian ligament and the tube within half an inch of the fundus, the other single and tying off the outer end of the broad ligament. The pampiniform plexus may give trouble, but I have seen it so degenerated as to pull to pieces in being tied. I use firmly twisted Chinese silk, and prefer to pass the ligature with a needle something like an aneurism needle, with a sharper point and longer handle than those found in the shops, to carry a double thread.

In tying, except in cases where one double ligature will suffice, I do not use Mr. Tait's Staffordshire knot, but I cross and interlock the two loops of all my double ligatures, and so far I have never had a ligature slip after the operation. After tying, before cutting off the tube and ovary, I catch the tissue with pressure-forceps close to the ligature, so that I can cut off my ligatures and not be tempted to use them to lift up the pedicle after being once tied. Besides enabling me to keep the pedicle in sight, these forceps act as guides in cutting away the tube and ovary. Often the ovarian ligament is so short that it is not easy to get a satisfactory stump left and cut off all the ovary. I like to have a Paquelin cautery on hand, so as to touch any suppurating end of a tube in a stump or ovarian tissue that may be left on it after tying. The tubes and ovaries of both sides should be removed if there is the least sign of salpingitis; but in two cases I found only the left side affected, the right tube and ovary being free from even a single adhesion, and I removed only those of the diseased side.

The cavity should be thoroughly dried with sponges and time given for hemorrhage to make itself manifest before the wound is closed. Where there are extensive adhesions or any pus cavity disturbed, or especially where there is any ascites, a drainage-tube should be put into the pelvic cavity. I prefer a large-sized tube of glass with some small holes in the sides besides the ends being open, and I use a large-sized catheter attached to an ordinary syringe for washing out the tube when needed. If there is no drainage I remove the large tube in thirty-six hours and slip a small rubber drainage-tube in its place, and the next day a still shorter and smaller one, each day until about the seventh day, when the opening will usually be filled up from the bottom. In introducing the sutures in the abdominal wall, I am careful to secure not only perfect coaptation of the peritoneal coats, but also of the deep and thick abdominal fascia, for if good union of this is secured the risk of ventral hernia is very much lessened; for it is this tissue and not the muscles, which are longitudinal, that gives strength to the abdominal wall in the median line. For thirty-six to forty-eight hours nothing is allowed to be taken except teaspoonful doses of water or broken ice, and enough morphine is used to prevent pain and restlessness, for several days. An enema is usually given on the sixth day to move the bowels, and sutures are removed on the eighth day. Either medium silk or silver wire is used in sutures for the abdominal walls.

If the abdominal walls are thick from adipose tissue, as a rule, the peritoneum will be found tense, and require more than usual care in closing properly. In such a case, after putting in from three to six silk sutures through the skin, fascia lata and peritoneum, the peritoneum should be carefully closed with catgut sutures, and the fascia lata also separately closed in the same way. Then the first silk sutures should be closed, leaving room between them, in two or more spaces, for short drainage-tubes placed upright so as to drain the adipose tissue between the fascia and the skin. Or if the walls are closed by silk sutures in the usual way, the skin, a little to the side of the cut, should be punctured so as to give vent to the grease that is certain to escape from the more or less bruised adipose tissue. I have seen mural abscess caused by this free fat, and it might enter the peritoneum and cause greater trouble. After sewing up and cleaning the wound, it should be freely sprinkled with iodoform and covered with a layer of absorbent cotton that has been squeezed out in one to five thousand mercuric bichloride, and over this several layers more of dry absorbent cotton, so that the whole abdomen will be evenly compressed when the adhesive straps and bandage are put on. Over the cotton a folded towel and mackintosh are placed, and firmly compressed by adhesive straps and a bandage. Except where a drainage-tube is inserted, this dressing can remain until the eighth or ninth day, when the sutures are removed, unless oozing appears through the dressing, or a rise of temperature takes place indicating septic poisoning, etc. In cases with extensive adhesions or in pyo-salpinx, especially where the tissues are infiltrated, we must expect a moderate rise of temperature during the first two or three days, caused by the small amount of septic material left in the pelvis; but this is readily absorbed and the local peritonitis caused by it soon subsides, and on the fourth or fifth day the temperature falls. When the case fails to rally well, and has a temperature at or below normal, or in some cases where all symptoms are favorable and temperature low until the afternoon of the third or on the fourth day, the temperature makes a steady rise, you have, as a rule, a fatal case of septicæmia to deal with, that death alone will stop—which it usually does inside of two or three days. Sometimes a case begins as a local peritonitis and gradually spreads to general peritonitis, vomiting, and death. Still, I think the proper name for such a case is septicæmia.

Complications.—As endometritis nearly always precedes salpingitis, it is necessarily a frequent complication. It is rare to find salpingitis uncomplicated by local peritonitis, and this, by the formation and contraction of bands of adhesions, distorts and displaces the pelvic organs and makes more or less permanent any displacement that

may have previously existed. This was fully brought out in describing the treatment. The most serious and dangerous complication is the rupture of a tube distended with septic fluid, causing general peritonitis and septicæmia. Should this happen and be diagnosed, or be indicated as the probable cause of peritonitis, it would be proper to open the abdominal cavity, remove the tube, and wash out and drain the peritoneum. The inflammatory process may become so intense in or about the tube as to cause the tissues to break down, and form so large an abscess that the surrounding tissues lose the power to protect themselves, and a perforation takes place into the rectum, vagina, abdominal wall, or through one of the openings in the pelvis, or into the bladder. This necessitates enlarging the opening to secure drainage, and often before a cure can be effected counter-openings are necessary, and if these fail, an operation for removal must be resorted to.

THE HISTORY OF MYXŒDEMA,

With the Report of a Case.

By D. F. KINNIER, M.D.,

RANDOLPH, MASS.,

LATELY CLINICAL ASSISTANT TO DR. COLCOTT FOX AT THE WESTMINSTER HOSPITAL AND VICTORIA HOSPITAL FOR CHILDREN, LONDON.

In 1873 Sir William Gull directed the attention of the Clinical Society of London to this disease, and called his cases examples of a "cretinoid state supervening in adult life in women." Dr. Ord, of St. Thomas' Hospital, next drew attention to this disease in a very able paper read by him at a meeting of the Royal Medical and Chirurgical Society of London in 1877. During the past ten years many cases of this disease have been reported, both at the English medical societies and in the medical journals.

During the past five years attention has been called to the disease in France, particularly by M. Charcot, who is credited with being the first to record a male example of this disease, and who disagreed somewhat with the teachings of Dr. Ord, as well as with the view of the relation of this disease to cretinism, put forth by Sir William Gull. M. Charcot, on account of the condition of the skin and the anæmia manifested by the disease, gave to it the term "cachexie pachydermique."

The causes of myxœdema are not very well understood. The great majority of cases have occurred in females, generally commencing at or about the climacteric, and frequently after confinement (Dr. Ord). Recently several cases of a typical kind, in which males were the subjects, have been fully described. In Dr. Andrew Clark's experience males have been the more frequent sufferers, in about the proportion of seven to three. Recent observations point to the central organs of the nervous system as being affected. Bulbar paralysis has been noticed in a few cases. From the histories of several cases collected by Dr. Ord, syphilis, alcoholism, and fevers do not play any important part in the causation of this disease. He found the disease more frequent in married than in single women. Pregnancy is supposed to be the cause in some cases. The majority of the cases observed by Dr. Bristowe were females; he considers the cause to be unknown. Dr. Ord's first case followed upon the fatal illness of a husband. In Dr. Cavafy's first case it followed a shock; in his second, a bad time at childbirth. In Dr. Duckworth's second case the patient said it came on after her husband had kicked and ill-treated her. In Dr. Semon's case the patient had fourteen children and many miscarriages in a short while. In Dr. Tom Robinson's case the cause is put down as pregnancy.

Dr. Mahomed has advocated the view that myxœdema is a form of chronic Bright's disease, but his views are at present disputed. A single typical example of this disease presents symptoms which are clinically very different from those of Bright's disease. Fatal cases have been reported which have terminated with albuminuria and coma, and in which, on post-mortem examination, the kidneys have presented an appearance very like that of chronic interstitial nephritis. But Dr. Ord says albuminuria rarely appears earlier than the last few months of the disease, and the patient may be entirely free from it for five or even ten years, although manifesting all the symptoms of myxœdema in a marked form. One case was shown me where the patient had been the subject of the affection for ten years. Charcot, as previously mentioned, has referred to this disease as the "cachexie pachydermique," and claims to have recognized it independently, although not the first to call attention to this disease. On becoming aware of Dr. Ord's previous investigations he adopted the name of myxœdema, yet some French writers still speak of the disease as the "cachexie pachydermique."

In the fatal case, successively under the care of Dr. Mahomed and Dr. Goodhart, there was no excess of mucin found after death, although the clinical symptoms during life were those of myxœdema. But there was found a small amount of jelly-like material among the muscular fibres. A few cases occurring in early life have been reported. Charcot showed one such case, but would not decide whether it was a case of late development of cretinism or early supervention of myxœdema.

At the Twelfth Congress of German Surgeons, held at Berlin in April, 1883, Professor Kocher, of Berne, the professor of surgery to the University of that town, read a paper on "Extirpation of Goitre and its Consequences." His personal experience was based on one hundred cases of total or partial extirpation of goitres, and was second to that of Professor Billroth. His attention was drawn to the after-condition of his patients by the report of the medical adviser of one of his patients, upon whom he had operated in 1874. Professor Kocher having seen this patient himself, was so much surprised to see the changes which had taken place, that he requested all his patients upon whom he had performed that operation, to present themselves for re-examination. The number who presented themselves was reduced to thirty-four.

In sixteen of these cases only partial extirpation had been done, one lobe, with or without the isthmus, having been removed. In all these cases the result of the operation had been very good, the dyspnœa, for which the partial extirpation had been performed, had disappeared, and the general health improved.

With regard to the other eighteen patients, on whom total extirpation had been performed, only two showed an improved state of health. In one of these two cases a small accessory thyroid gland had become hypertrophied, and in the other case the goitre had returned. The other sixteen cases showed a more or less poor condition of their general health, this condition being most marked in the cases earliest operated upon. Professor Kocher, speaking of the changes, says: "A few months after the operation early fatigue, weakness and sensation of heaviness in the limbs were complained of. In many cases these were preceded by pains in different parts of the body. Soon afterward a sensation of coldness, especially in the extremities, was superadded. In winter time the hands and legs swelled, became bluish-red and cold, and the patient suffered from chilblains. The mental activity decreased; thought, speech, and movements became slower."

At the same time the patients themselves were aware of these facts. Simultaneously there appeared swellings of the face and body, being at first only transitory, but soon became lasting features. The parts most and earliest affected were, as a rule, the infra-ocular region and the eyelids, which showed a somewhat transparent swelling. Later on the nose became thick, the lips coarse, hands and feet swollen, and the waist stouter; the skin became dry, desquamated a little, and its elasticity was lost; it could only be lifted in thick folds; the hair fell

out. A more marked symptom in the more progressed cases was anæmia. The blood showed a richness of leucocytes, and a great diminution of the red blood-corpuscles. In cases in which the patients at the time of the operation were still growing, the development became arrested after the operation. Rarer symptoms were: slight dysphagia, giddiness, and headache. Ophthalmoscopic examination, made in a number of cases by Professor Pflüger, revealed nothing abnormal beyond an abnormality of the arteries. Being at that time unaware of the existence of myxœdema, he proposed for the affection he described the name of cachexia strumapriva.

Observations similar to these had been made by Professor Reverdin, of Geneva. Dr. Semon relates a case in which Professor Lister removed the whole of the thyroid body, when a set of symptoms similar to those described by Professor Kocher followed a few years after the operation. In the three conditions, viz., cretinism, myxœdema, and the state supervening after total removal of the thyroid body, certain conditions of arrested development of mind and body were met with, which, looked upon in the light thrown upon the subject by Professof Kocher's observations, could hardly be attributed to anything else than the loss of the thyroid body common to them all. The theories as to how these changes are brought about, and the influence of the thyroid body upon the composition of the blood and other tissues are at present contradictory and inadequate. One hypothesis has been put forth, viz., if the absence of the thyroid gland would lead to arrested development of mind and body, it might also lead to arrested development of the higher forms of organized tissue—the fetal tissue—and that then mucin would mainly be formed. Hence the presence of an excess of mucin in the tissues, which had been supposed to be the essential feature of myxœdema, might perhaps find its explanation.

The symptoms of myxœdema are various and numerous. One of the chief features of this disease is the peculiar physiognomy manifested by the patient. The face is swollen, so as to suggest the existence of renal disease, with which cases of myxœdema were confounded before the disease was well understood and recognized. As a rule the œdema is general, but is most marked in the hands and face, especially the lower eyelids. Pressure on the œdematous parts does not produce pitting. The lips are thick and enlarged, the alæ nasi are similarly affected. The tissue around the eyes appear swollen, puffy, and colorless. The skin is waxy-looking and anæmic, the lips present a faint pinkish tint, and the cheeks are marked by a dull pink flush, which shades away toward the orbits. This flush on the cheek is circumscribed and persistent. The hands are large and thick, their shape altered, and, as Sir William Gull describes them, "spade-like." This condition of the hands is probably due to the fact that the fingers become thickened and flattened by pressure against each other. The conditions of the body generally are similar in appearance to those of the face.

The skin is dry and rough to the touch, and is thicker than the skin in health; in some cases the skin is smooth and delicate looking. The speech is slow and thick, resembling that of a person affected with quinsy. The tongue appears enlarged, and this condition may in part explain the peculiar speech. The inside of the cheeks is thickened and of an œdematous condition. The movements of the limbs are slow, the gait uncertain, the legs sometimes give way and the patient falls down; an effort is required to maintain a fixed position. The patient is slow in thinking; a distinct hesitation is noticed before answering questions. Much longer time is required in doing work, whether mental or bodily, than is required for the performance of the same in health, the patient also seems to lose all interest in what is going on around her. She oftentimes expresses herself well in both speaking and writing, but at other times appears to be at a loss what to say. The special organs are not affected, and the muscles appear normal. The internal organs are not necessarily affected.

The urine does not contain either sugar or albumen; specific gravity is lowered. There is sometimes a slight, at other times great, difference in the amount of urea passed in the twenty-four hours. As a rule the urea is largely increased. Authorities differ as to the amount of urea eliminated in the twenty-four hours, some reporting cases where the urea was subnormal, others where it was greatly increased. Cases are reported in which the amount of urea passed in the twenty-four hours was from ninety to one hundred and eighty grains, as estimated by the ureaometer.

The patient complains of feeling cold, and the bodily heat is often lower than normal, the temperature in the axilla varying from 96° to 98° Fahr.

In the cases reported by Dr. Ord, as the disease advanced the viscera became affected, and albumen was present in the urine in the last stages of the disease. Late in the disease the mind becomes affected. The patient is irritable and fretful; finally coma supervenes. In cases observed by Ord and Bristowe death terminated in coma or symptoms of uræmic poisoning.

In the two fatal cases observed by Dr. Ord, albuminuria was present before death, and may have been connected with the cause of the death of the patient.

The chief morbid condition discovered by Dr. Ord was general œdema of the connective tissue, including that of the lungs, heart, and kidneys. Mucin was found in very large quantities in the tissues, and it was the presence of this peculiar substance in them which led Dr. Ord to give to this disease the name myxœdema.

The thyroid body has been noticed to atrophy in the course of the disease. Dr. Kocher, of Berne, had noticed that after the total extirpation of the thyroid gland in numerous cases, a number of symptoms had developed in these cases very like those of myxœdema. It had also been noticed by Professor Kocher, that in those cases in which the operation had been performed when the development in the length of the body had not yet been completed, the development had become arrested.

Dr. Felix Semon, about two years ago, directed the attention of the Clinical Society of London to Professor Kocher's cases, and suggested that myxœdema might be more closely allied to cretinism than was supposed, and that myxœdema and cretinism might represent different stages of the same affection, cretinism arising either during the period of intrafetal or intellectual development, myxœdema, on the other hand, being essentially a disease of adult life.

Kocher's cases, however, did not seem to strengthen these views of Dr. Semon. Recently Professor Paul Bruns, of Tübingen, called attention to a paper of his "On the Present State of the Treatment of Goitre," in which he communicated the case of an individual, now twenty-eight years old, whose thyroid gland had been removed eighteen years previous on account of goitrous degeneration. One year after the operation, Dr. Sick, of Stuttgart, had drawn attention to the fact that a marked physical change had taken place in the boy; he had become unusually quiet and retired, having previously been a bright and lively child. Professor Bruns having looked up the patient, found him still living, but he had become a dwarfy cretin. The development in the length of the trunk and limbs had entirely become arrested since the operation, and only the dimensions of the head were those of a man of his age. The total length of the body was five feet two inches.

The expression of the face was that of an idiot; the face was much swollen, especially the lips and lower eyelids; the skin and visible mucous membrane was pale. The skin over the whole body was dry and brittle; the hair was scarce and thin on the head; no trace of a beard, and but few pubic hairs; genital organs were well developed.

Partial extirpation of the thyroid body is said to be not

followed by myxœdematous symptoms. These facts seem to point out that it was the loss of the function of the thyroid gland which caused both cretinism and myxœdema.

The prognosis is unfavorable, the period of life varying from five years and upward.

Regarding the treatment, Dr. Bristowe says it can only be palliative. Dr. Ord has found benefit from vapor-baths, and still greater success from the use or jaborandi, and in a few cases he treated by this drug he found the signs of the disease had very much disappeared. The dose of jaborandi generally given is ten, twenty, or thirty drops of the tincture (B. P.). Pilocarpine subcutaneously may be used, commencing with one-twelfth of a grain and increase until the required diaphoresis is produced. When hot-air baths fail to produce diaphoresis trial should be made either of jaborandi or pilocarpine. Nitro-glycerine is also recommended and given with the object of diminishing arterial tension. Dr. Mahomed used this drug in a case under his care attended with albuminuria, but the improvement was only temporary. Charcot relates a case that so much improved under the prolonged use of milk diet, as to lose some of the marked features of the disease. Dr. Andrew Clark regards the disease as greatly benefited by care in diet, and use of arsenic, iron, baths, and friction. Iodide of potassium, strychnine, phosphorus, have been tried. Cases have been reported where the patients showed improvement independent of drug treatment.

The following case I saw at the London Hospital, under the care of Dr. Stephen McKenzie: J. A——, an unmarried woman, aged thirty-five, came to Moorfields Eye Hospital in February, 1884, as an out-patient, under the care of Mr. Gunn. She complained of swelling of her eyelids, which had gradually increased for nine years. She was one of a family of nine, none of whom had shown symptoms resembling hers, her four sisters, all older than herself, being in perfect health.

Her father died in old age; her mother at fifty-seven years with hemorrhage from stomach. No history of hæmophilia in the family. The patient was always well-cared for. For the first twenty-three years of life she had enjoyed very good health, when seventeen years ago she had two teeth extracted, the bleeding after the operation lasted twenty-four hours and was very copious. She said she had never been well since. No marked symptoms were noticed till twelve years ago, since which time tney had steadily increased with occasional slight remissions. The patient presented the characteristic facies of myxœdema as described by Dr. Ord. The loose, baggy, almost translucent lids; the dry, brawny cheeks and thick blue lips, with the swollen, red, expressionless hands, and deliberate speech and volition made a group of symptoms which once seen could not be forgotten. Her heart and lungs were sound, her digestion somewhat affected. Her molar teeth had broken off bit by bit, her gums were extremely vascular and bled freely, so that her mouth was frequently filled with blood in the morning. Her extremities were always cold, and her axillary temperature always subnormal. Her urine varied much in quantity; but scanty or copious the total amount of urea was invariably deficient, only rising to half the normal amount, and frequently being as low as one-fourth. It contained neither sugar nor albumen. She began to menstruate at the age of fourteen, and had menstruated regularly; the amount had always been copious, but sometimes the flow might last for three weeks, leaving her very exhausted. With the exception of deliberate speech, thought, and volition, there were but one or two points to be noted in connection with her nervous system. One was the constant recurrence of a nervous restlessness, so that she was afraid when the night came, as she could not lie still

As regards treatment the usual tonics seemed to have no effect. A short while after her admission she was put upon half-drachm doses of tincture jaborandi, which she continued for three weeks, at the end of which she left the hospital. The patient said she felt better while taking the jaborandi, and this treatment increased the amount of urea excreted until it was double the normal amount.

IMPRESSIONS OF THE CHOLERA AND ITS TREATMENT DURING THE RECENT EPIDEMIC IN FRANCE.

By BENJAMIN D. HOWARD, A.M., M.D., F.R.C.S.E.,

LONDON, ENGLAND.

THE general statistics of the recent epidemic, fortunately so limited and brief, are now as undisputed and as unattractive as a last year's almanac.

The impressions and lessons from a prolonged personal experience, however, in that epidemic may have an interest still fresh, and which unfortunately may increase as the winter recedes and the summer approaches.

The nature of the epidemic. In the rough its Asiatic character has, as we all know, been long accepted universally as beyond dispute. Regarding its exact type in comparison with that which prevailed in Paris in 1865, and in New York in 1866—both of which epidemics I happened also to have a personal acquaintance with—the recent epidemic in Paris was, I think, more malignant. Premonitory diarrhœa was more infrequent; collapse occurred earlier; death quicker. In case of recovery, the symptoms generally assumed a typhoid character, delaying greatly the completeness of the recovery. Literally struck with the disease—seized at once with the symptoms of approaching collapse—I saw more than one patient die within six hours of the commencement of the attack, no sign of possible reaction having once appeared from the beginning to the end. One man I saw taken in this manner while he was promenading on the Boulevard, in whom the symptoms were so conspicuous, even to the cabmen, that of eight or ten called, not one would take him or his fare.

The question now most conspicuous and pertinent is, What has this epidemic yielded in the way of improved treatment? There are three remedies, the value of which have been more or less taught or confirmed: Inhalation of oxygen, transfusion of saline solutions, and the spinal ice-bag.

Inhalation of oxygen.—The Hospital St. Antoine, which had by far the larger number of cholera patients, was equally notable for the enterprise and enthusiasm in their treatment. Professor Hayem, the physician-in-chief of the contagious diseases service, with M. Bufflorg, his *chef-de-service*, concluded that as Professor Hayem had found such utility in the vomiting of pregnancy from the inhalation of oxygen, it might be well to try it in the cases of most persistent vomiting in cholera. When any ordinary internal remedy would have been at once rejected, the inhalation of oxygen, which is without risk or inconvenience, seemed in almost every case to diminish the retching and vomiting, and at the same time somewhat diminish the sense of coldness. When ice pellets, sinapisms, Badejon phenicæ blistering fail, it is worth knowing that the inhalation of oxygen may stop the vomiting quickly and entirely.

Transfusion.—In collapse with complete pulselessness this remedy, particularly at St. Antoine, was largely employed, and with great skill and enthusiasm. This operation was generally preceded and followed by a hypodermic injection of ether. The apparatus used was Rousel's. The solution generally used consisted of sodæ sulph., 10 parts; sodæ chlorid., 5 parts; and distilled water, 1,000 parts, at a temperature of 39° C., two or three litres being transfused in adults at one operation, this being repeated in some cases three times at intervals as seemed expedient. The results of this operation were nearly always very striking, and in one respect curious.

After twenty or thirty strokes, each stroke injecting twenty-six grammes, the lost pulse would return, followed by an almost startling brilliance of the eyes, partial restoration of the voice, and a general appearance of improvement in other particulars, with one exception. Curiously enough, after the fiftieth or sixtieth stroke, the patient would usually complain of feeling colder; this complaint would often be corroborated by severe chills, which would sometimes be so persistent as to reach their height not till half an hour after the operation.

The urine, on its reappearance after transfusion, was apt to be for a time slightly albuminous.

The spinal ice-bag treatment.—This, I am glad to say, my friend, Dr. Chapman, had an opportunity of trying at La Charité, with a limited and small number of patients. From Dr. Chapman's experience with this treatment in a previous epidemic in Southampton, Professor Peter was induced to invite Dr. Chapman to try his method as I have stated. I did not see the patients while thus treated, but Professor Peter has expressed his satisfaction with the results. The extent and elaborateness of the system constructed by Dr. Chapman, upon the hypothesis of vaso-motor regulation and control by means of given temperatures applied to the spinal column, have doubtless hindered its acceptance. While nobody can deny the ingenuity of the theory, many hesitate to accept conclusions so extensive. By the recent experience at La Charité one practical point in connection with Dr. Chapman's theory has, so far, doubtless received demonstration.

The difference between the treatment here in 1865 *and* 1884.—This, with the above-mentioned exceptions, is slight. Bismuth is used as before, but in grave cases in the form of the salicylate; for cognac have been largely substituted wine and water, eau de seltz and water, with bicarbonate of soda; for opium, laudanum; and for friction, hot flannels.

The progress made in the early treatment.—This cannot be said to be very great, and is too well illustrated by the following fact: A friend of mine, of the Faculty of Paris, who has greatly distinguished himself in his microscopical and other investigations in connection with cholera, was complaining of very troublesome borborygm and diarrhœa after unusual exposure in the cholera wards. In response to my anxious questions he informed me it was all right, that he had taken five grains of bismuth, and in answer to "Why bismuth?" "Well, you see, bismuth is innocuous; it acts mechanically, it coats and protects the diseased part." How five grains of bismuth could be so directed as just to cover the diseased part, and that only, implies a skill beyond my comprehension.

The practical lessons from this recent experience respecting treatment.—The general tendency to the adoption by preference of one method of procedure, and that alone, is for the patients a great misfortune. Should it become my duty to direct the treatment of cholera patients hereafter, without now pretending to state all I would do or avoid, I am quite sure I should use what in Paris I have never seen employed, *i.e.*, hot-air bath, the tube from the ordinary spirit-lamp apparatus projecting under the bedclothes in every case. While this maintained the general heat of the bed, hot bottles, hot flannels, and friction should be duly employed also according to symptoms. The supply of eau de seltz or other saline agreeable drink should be limited only by the desire of the patient to swallow it.

Oxygen for inhalation should be constantly available, to be used in conjunction with or without ice pellets and sinapisms, as might or might not be expedient.

Transfusion appliances should be always ready; but for the chills supervening I would supply extra applications of hot air, hot flannels, friction, and hot drinks, if the latter could be borne.

Typhoid tendencies I would meet as in any other case, but with extreme delicacy and caution.

In a certain proportion of cases, not very severe, I should be tempted to try the spinal-ice bag, holding myself ready to relinquish it and to combine or substitute other measures at any moment.

The pathology of cholera.—As regards general lesions there has been nothing to remark; in only one instance did I observe any ecchymosis of the intestines. The microscopical conditions are too familiar for remark, each of the particular phenomena has of course been seen in the laboratories, and should others be described, doubtless they would be seen also.

The communicability of the cholera is a question upon which unanimity can scarcely be expected. To assume that the coma or any other bacillus is the one and only essential germ of cholera, and that this must reproduce itself or nothing, is doubtless premature. Practically our concern regards the soil as much as the seed, and the means of sowing are many. During this recent epidemic it is said not one hospitable physician or interne has had cholera. Admitting this to be true, the same may have been said many times concerning typhoid fever, scarlet fever, and small-pox. Further, while none of these fortunate individuals had typical cholera, I do not know one interne who had much work in the cholera wards but who, during the greater part of the time suffered from borborygm, colic, diarrhœa, and in a manner unknown to him under ordinary circumstances.

Mr. McNamara relates how, in 1872, having in the morning been engaged in a close laboratory examining some monkeys to whom he had given cholera dejecta, before four o'clock of the same day both he and his assistant were attacked with cholera, extending afterward to collapse. In connection with the point I have mentioned, that many of those visiting cholera patients, though continuing free from typical cholera are victims of very disagreeable intestinal disorder, I may mention one fact which came immediately under my notice. A medical friend, in robust health, the day of his arrival in Paris from the seaboard, was with me for about two hours in some rather close single cholera wards. Within one hour of his leaving the hospital he had involuntary diarrhœa, and for the several remaining days of his attendance in cholera wards, borborygm, colic, and offensive diarrhœa persisted in spite of treatment, and continued four or five days after his return home. The day after his return his wife, from whom he had kept his hospital visits secret, was affected, and continued precisely the same way for five or six days; neither the one nor the other had what could be called cholera, but what both of them had could be traced to no other cause than the attendance of my friend upon patients who did have it. This is but one of several similar facts which have come recently under my observation, showing, as I think, that the essential element of cholera may have many varieties and infinite degrees of effect, according to the condition of the respective individuals, the most perfect adaptation and susceptibility existing only in a small minority of those who have been gradually prepared by continuously bad hygiene or pernicious habits.

Toulouse being the only city on the European continent to this moment having a single accident horse-ambulance, patients going to hospital went there as best they could, usually, of course, in the first public cab that would take them, the few ambulance wagons for contagious cases having been used chiefly for returning these patients to their homes after they were considered sufficiently recovered. So that while something was done to limit the spread of the disease, enough was left undone to allow it to extend itself, if it could do so, to any or all of the immense cab-hiring community of Paris.

The Medico-Legal Society held its annual meeting on Wednesday evening, January 21st, at which the President-elect, Dr. R. Ogden Doremus, gave his inaugural address. The members then attended the annual banquet at the Murray Hill Hotel.

HORSE-HAIR SUTURES AND DRAINAGE.

By DANIEL LEWIS, M.D.,
NEW YORK.

In a short paper on the advantages of horse-hair for sutures and drainage, presented before the Medical Society of the State of New York at its last meeting, I mentioned the fact that Mr. Purcell, of London, often leaves such sutures in the wound for ten days without the slightest detriment. This has been so well exemplified in a recent case in my service at the New York Skin and Cancer Hospital, that a brief note of it may be interesting. The patient had recurrent cancer in the cicatrix of the former breast amputation, as well as in the axilla. An incision was made from the sternum to a point behind and below the axillary space, and a vertical incision to the armpit. All the axillary glands were removed, and, of course, the operation was a tedious one. Something of a pocket remained in the dependent portion of the flap, in the bottom of which a puncture was made of sufficient size to pass a bundle of horse-hair (about the size of the ordinary rubber drainage-tube), which bundle extended the entire length of the wound, about eleven inches. Black carbolized horse-hair sutures were then used to close the incisions, by the continuous stitch. Drainage was as perfect as could be desired. A small portion of the sutures was removed on the seventh day, because union was complete at the sternal end, and the remainder was removed on the tenth day. *No* suppuration around the sutures had occurred, a result which we would hardly expect with the use of any other material. The drainage had been gradually removed, hair by hair, and the last dispensed with on the tenth day also.

I have never seen such a satisfactory result in the same length of time in so difficult an operation, and there can be no doubt that the material used was the most important contributor to this end.

Some care should be taken to select good hair—if too fine it may not be strong enough—if very coarse it is sometimes brittle and may break in tying. Black hairs are more readily seen, a great advantage when you come to remove them, and they should be carefully washed and disinfected. During the past year I have continued the use of these sutures, and in a large variety of cases, the results being so satisfactory that silk and wire have been almost discarded.

It seems fair to class these uses of horse-hair among the minor improvements in surgical dressings, which, taken together, are the chief factors in securing success, and for this reason I have taken the liberty of again calling attention to the subject.

147 East Forty-fifth Street, December 26, 1884.

"Carbonate of Titanium."—A writer in *The Medical World* recently recommended in the strongest language a certain pill "used by the French women to produce barrenness," as a remedy for amenorrhœa. A married woman using this pill, says the writer, does not become pregnant. The formula is as follows:

"℞. Pulv. aloes (soc.),
Carb. titan.....āā 3 j.
Fiant pilulæ No. xxx.
Sig.—One pill three times daily.

No particular nicety need be paid in regard to dose; from one to three pills may be taken *ter die*." Dr. A. B. Lyons, of Detroit, Mich., suspecting some crookedness, sent for some of the carbonate of lithium. On examining an alleged specimen he found that it consisted of about equal parts of sulphate and subcarbonate of iron, with a little bloodroot. The vaunted pill, therefore, is nothing more than the ordinary pil. ferri et aloes.

THE CURE OF ASTHMA.

By RICHARD B. FAULKNER, M.D.,
PITTSBURG, PA.

I understand by the term asthma the condition of spasm of the bronchial tubes of both lungs, with hyperæmia approaching or amounting to inflammation, accompanied by râles upon both inspiration and expiration, with great difficulty of breathing. And the term is applied to the paroxysm alone, which returns at regular or irregular periods. Disturbance of function or disease of structure of the pneumogastric nerve is always present. And without detailing its anatomy, I advise close reference to Gray, in all instances of the affection in which the cause is obscure. Generally symptomatic, yet often independent asthma finds place in the nosologies of Niemeyer, Salter, Watson, Trousseau. An evolution of the neurotic constitution, it is generic with neuralgia and the spasmodic cerebro-spinal neurosis. Trousseau considered his own case inherited. He saw asthma, neuralgia, gout, rheumatism, cutaneous irritations, and hæmorrhoids, alternate one with the other. Indigestion, imperfect nutrition, anæmia, chlorosis, syphilis, occasionally cause it. It is frequent in the spring through association with respiratory diseases. I have never known phthisis to be the cause or associate of asthma. Thousands of cases of naso-pharyngeal catarrh exist without causing it. Nothing tends more to asthma than disorder of the skin. In fact, I have not known of a case in which the action of the skin was normal. With no desire to magnify its importance I must refer to its delicate anatomy, and speak of its wonderful vascularity, exquisite nerve-supply, and of its vast sudoriferous and sebaceous systems, and then of its important functions—sensation, absorption, and secretion. When the skin has lost its tone, every slight exposure is apt to excite abnormal impressions, occasion vaso-motory disturbance with internal congestion and reflexive irritation of the bronchial nerves.

Asthma prevails mostly in the fall, because of the enervation of the nervous system wrought by the long-continued summer's heat. Its prevalence can be approximated by the amount of its mortality. By a table I have formulated, I have shown, first, the actual leath-rate in many cities, and by inference, its prevalence; second, that the mortality is maximum in warm climates; third, that its origin is independent of consumption, pneumonia, and bronchitis.

I heard the venerable Alonzo Clark tell his class, to which I belonged, that the climate of Pittsburg was thought to be especially salubrious for asthmatics on account of the smoky condition of its atmosphere. Indeed the enormous quantities of smoke generated by her immense rolling-mills, blast-furnaces, and glass-houses, render the atmosphere so hazy that the sun often resembles the moon until the morning is half over. Carbonaceous collections are seen in the inner canthus of every eye, in every nostril, and are coughed from every throat. Dr. Hyde Salter wrote, in Reynolds's "System of Medicine," vol. ii., p. 107, American edition, that, "in the great majority of cases, an urban residence is best for asthma, and especially that part of the city in which the air is densest and smokiest. As a rule the air of a low situation is better than that of a high one, and a relaxing air than one that is bracing." My observation condemn his teachings. What is smoke? Finely divided carbon. But an atmosphere of smoke contains also the noxious gases generated by combustion, namely, sulphurous acid, carbonic acid, nitrogen, and hydrogen. These gases are very irritating to the mucous membranes. The grate in my consultation-room smoked once when asthmatics were present, and caused immediate dyspnœa. Smoke greatly influences the air; attracts and condenses moisture; produces fog and rain. This is emphasized by the fact, pointed out to me by the distinguished astronomer, Professor Samuel P. Langley, Director of Allegheny Observatory, that "in Pittsburg there is

little rain on Sundays, because the mills are then shut down, and the atmosphere is clear. Sundays are generally clear and dry. If it were not for the smoke in this city there would be much less rain. Considering altitude alone the air of Pittsburg should be light and dry." When Salter and others refer to the air of certain parts of a city as being "*denser* and smokier" than other parts, they speak only seemingly to the senses, not literally.

"SIGNAL OFFICE, WAR DEPARTMENT,
WASHINGTON CITY.

"SIR: Relative to the effect of the smoke of Pittsburg on local barometic pressure, I have the honor to say that the mere smoke of a city cannot have any appreciable effect upon barometic pressure.

"Your obedient servant,

"W. B. HAZEN, Brig. and Bvt. Maj.-Gen.,
"Chief Signal Officer, U.S.A."

The influence of smoke upon temperature is not known. Pittsburg has sudden and extreme changes in temperature. Smoke is very diffusible and soon affects the atmosphere for miles around.

"ALLEGHENY OBSERVATORY,
ALLEGHENY, PA., January 12, 1884.

"DR. R. B. FAULKNER—*Dear Sir:* I have been informed by Mr. Clarence King, Director of the United States Geological Surveys, that the smoke of the Chicago fire was seen on the Pacific coast.

"Yours truly, S. P. LANGLEY."

The prognosis of asthma turns upon its complications. The malady sometimes persists through the force of habit.

To cure the paroxysms I originated a method of treatment nearly five years ago; and repeated observation has confirmed its great utility. When called to a case of asthma, with a camel's-hair brush I make a streak of Churchill's iodine *over each pneumogastric nerve, in its course in the neck, from the upper part of the thyroid cartilage to the upper borders of the clavicles.* By counter-irritation thus applied, the capricious and abnormal exercise of nerve-force by the pulmonary filaments is controlled, and bronchial spasm promptly relinquished. Such is my original method—simple, certain, quick. Churchill's tincture is the best counter-irritant, because, first, it is convenient; second, its action is easily controlled; third, it does the work. To permanently cure the paroxysms, it is usually necessary to remove the underlying morbid condition upon which they depend or are associated. Remove bronchitis, correct emphysema, strengthen weak cardiac impulse, attend to indigestion, etc. It is cardinal doctrine to keep the skin active. With it dry, harsh, sallow, insensitive to healthy impression, incapable of proper transudation, it is no wonder that many do not recover. Soap! water! friction! Daily salt water baths. Respiration is somewhat assisted by Politzer's inflator, or Waldenburg's machine. An elastic rubber tube, two feet long, is excellent for ladies to exercise with, and strengthen flabby muscles. Dumb-bells; Indian clubs. Away from low, damp parts of a city; seek the *suburbs*. *Suburban residence* is best. Away from the enervating South to the cool and bracing North. Go to New England, Canada, Eastern Colorado, Utah, Northeastern Montana, Minnesota, Oregon, Southern California coast. San Diego, Los Angeles, Salt Lake City are desirable. Go where the atmosphere is light, cool, and clear. As that keen philosopher and sound pathologist, the great Niemeyer, said, "It is desirable that all asthmatics should reside in a pure, dry atmosphere; and avoid dusty, smoky, and windy localities."

36 NORTH DIAMOND STREET.

SOME OF OUR DENTISTS are using muriate of cocaine in their practice, claiming to be able to fill cavities and to use the dental engine without causing pain.

Progress of Medical Science.

UNILATERAL SPASM OF THE TONGUE.—Dr. E. C. Wendt reports, in the January number of *The American Journal of the Medical Sciences*, a case of unilateral lingual spasm. Symptomatic spasm of the tongue has been frequently observed in a great variety of diseases of the nervous system, but the idiopathic occurrence of such a disturbance is quite rare. Dr. Wendt's case was that of a man, aged thirty-six. He was of excellent physique and good antecedents. The right side of his tongue was alone affected by paroxysms of spasm, lasting from one-half to several minutes. The intervals were free from morbid manifestations of a decided character, although he complained of some soreness about the right tonsil. There was found by a specialist some deviation of the nasal septum, hypertrophy of turbinated tissue anteriorly, and chronic irritative hyperæmia of the larynx. The patient's sense of taste was perfect, as were also the other special senses. The lingual twitchings were not painful, but at times interfered with speech. Various remedies having proved useless, a cure was finally effected by the daily application of galvanism to the tongue, in a period of two weeks

THE USE OF THE ASPIRATOR AFTER TRACHEOTOMY.—So frequently does it happen that disease and death follow the removal of secretions from the trachea by suction, that, before resorting to it, a thorough trial of all other means at our command should be made. Dr. Dupuis cites a case in the Canada *Lancet*, December, 1884, in which two of his assistants contracted diphtheria in this way. He has used, and recommends, the aspirator in similar cases. A small tube, about eighteen inches in length, is attached to the instrument in place of the needle. This is introduced through the tracheal wound as often as accumulated secretion causes trouble. A writer in the London *Lancet*, November 8, 1884, after claiming to have used the aspirator in this way during the past nine years, alludes to the defects in the apparatus owing to the air being drawn into the trachea by the side of the suction-tube, and recommends the addition of a piece of wash-leather about 6 x 6 to the tube. A piece of vulcanite tube is passed through a small hole in the centre of the wash-leather, which is tied firmly. The suction-tube is then passed through this and into the trachea. The wash-leather is moistened and spread over the neck of the patient, and effectually prevents the entrance of air alongside the tube.

SULPHATE OF COPPER IN OBSTETRICS.—Dr. Charpentier, of Paris, has proposed the use of copper as a local application in obstetric practice. *L'Abeille Médicale*, November 17, 1884, gives the following as his conclusions: Sulphate of copper employed in solution of one to one hundred is an antiseptic of the first order, which can render great service in obstetrics. Absolutely inoffensive to the patient, of a very moderate price, and easy management, it joins to the advantages of being a very powerful antiseptic that of being an almost instantaneous disinfectant. Whether it be employed as intra-vaginal or intra-uterine injection, it is absolutely innocuous. It possesses astringent and coagulating properties to such a degree that it can be substituted as a hæmostatic for the perchloride of iron, over which it has the advantage of not leaving a foreign substance in the wound. The solution should be heated to 100° F. Its use can be continued during the first eight or ten days, several times in the twenty-four hours, without other effect than lowering the temperature and diminishing the frequency of the pulse. The author has had excellent results with the copper solution in large thrombus of the vulva, fetid abscess of the urethro-vaginal fold, and similar conditions, cutting short the general symptoms resulting from the putrid infection, and bringing about rapid healing, where phenic acid solutions had failed.

Bilateral Spinal Sclerosis Consecutive to a Unilateral Lesion of the Brain.—From a careful study of ten cases Dr. A. Pitser arrives at the following conclusions: 1. Consecutive to unilateral lesions of the brain, it is not rare to find secondary sclerosis of the spinal cord involving symmetrically the two lateral columns. In these cases the sclerosis follows the course of the pyramidal fibres through the cerebral peduncle, the pons, and the anterior pyramid of the affected side, but below the point of decussation the sclerosis suddenly becomes bilateral. 2. The medullary lesions below this point are sometimes perfectly symmetrical, that is, of equal intensity and extent, and at other times are more marked on the side of the hemiplegia. The columns of Türck are generally unaffected or involved but slightly and partially. The other portions of the cord are normal. 3. This bilateral sclerosis of the cord secondary to unilateral lesions of the brain, is due in all probability to some anomaly of decussation of the pyramids. 4. All the bilateral symptoms in hemiplegia of cerebral origin are not necessarily dependent upon the secondary cord lesions here described. Loss of power in the limbs of the non paralyzed side is a common symptom in all cases of hemiplegia, due to a destructive lesion of the brain. Bilateral exaggeration of the patellar tendon, reflex and bilateral contractures of the lower extremities may be met with in cases in which the secondary sclerosis is confined to one side; and may again be absent when the secondary sclerosis involves both lateral columns. But the disturbances of equilibrium and of locomotion seem to be more permanent and more marked in cases in which both columns are affected than when the sclerosis is unilateral. —*Rivista Clinica*, November, 1884.

Hot Water in Constipation.—Water at a temperature of 140° F., taken in moderate amount at intervals of fifteen to twenty minutes, and drunk slowly, is said to be a powerful exciter of peristaltic action and a diuretic. It frees the stomach and intestines very promptly of acetic and butyric acids, of lactic acid in excess, and of ammoniacal products. The stools become frequent and bilious in character.—*Memorabilien*, November 20, 1884.

Unsuccessful Excision of the Initial Sore in the Prevention of Syphilis.—Dr. Rason reports the case of a healthy lawyer, twenty-eight years of age, who came to him with the request that he would examine a woman with whom he had had connection two days previously. She was found to have mucous patches on the genitalia, evidences of an old chancre, and also roseola. A month passed during which the man observed the greatest cleanliness, and was also frequently examined for the first signs of a sore. On the morning of the twenty-eighth day after coitus the patient presented himself with a bluish red spot scarcely at all raised, about the size of a hemp-seed, on the inner side of the prepuce. Dr. Rason advised excision and performed it at once with scissors. The sore suppurated a little, and after twenty-five days became indurated about the edges. In forty-eight days after the excision, seventy-six after coitus, roseola appeared with mucous patches in the throat. Professor Ördmannson, of Stockholm, has had a similar want of success, though he believes that the subsequent course of the disease is lighter after excision of the chancre.—*Norsk Magazin for Laegevidenskaben*, No. 10, 1884.

Progressive Ossifying Myositis.—Kümmel regards this affection not as a pathological curiosity, but as a well-defined disease, in regard to the nature and etiology of which, however, there are still many points requiring elucidation. He has found twenty-seven cases recorded in the literature, and relates another coming under his own observation. The child presented from birth a marked deformity of the back with limited motion in several joints. At the age of two years he had an attack of fever which was followed by the appearance of several tumors on the back, at first soft, and later hard. From this time the disease progressed slowly up to the twelfth year, the osseous tumors became more numerous, and motion was limited in a progressively larger number of articulations. All the affected muscles showed a diminished sensibility to the induced current. Kümmel believes that the disease is congenital in its origin. In general it may be said that the affection begins in a simple infiltration of the intermuscular connective tissue, at the commencement of which there is a feeling of semi-fluctuation. Later there occurs a fibrous induration, that is, a hyperplasia with consecutive diminution in the volume of the muscle, and soon after ossification begins. The author was able to determine by microscopical examination that the process consists not in a simple calcification of the muscular mass, but in the formation of a true osseous tissue covered with a layer of cartilage. Some of the tumors seem to be true exostoses, being attached to some part of the bony framework, while others are isolated and due to a metaplasia of the connective tissue. The disease may attack symmetrically most of the muscles of the body, commencing with the dorsal muscles. The fingers are rarely the seat of the affection. As regards treatment the author advises baths, mercurials, and iodide of potassium, remedies which are at least palliative, even if not curative of the disease.—*Rivista Clinica*, No. 10, 1884.

Law of Heredity of Cataract.—In a reprint from the *Revista de Ciencias Médicas*, Dr. D. Luis Carreras-Aragó gives a table showing a remarkable instance of the hereditary transmission of cataract through several generations. In two branches of the family, extending through three generations, seven of the children suffered from cataract, and of these seven every one was a female. None of the boys of the family were afflicted. From a study of these cases, and of others recorded in the literature of the subject, Dr. Aragó concludes that hereditary cataract is transmitted by preference to the individuals belonging to the sex of the original ancestor. He expresses the hope that others will record their observations on this point, in order that, if the law of heredity be as he believes, the fact may be established.

Is Herpes Zoster Contagious?—Dr. Klamann relates the following case: A boy one year old suffered from herpes zoster on the left cheek. When the vesicles began to dry up there appeared a similar eruption on the mother's right cheek, against which the child had usually rested its head while it was sick.—*Norsk Magazin for Laegevidenskaben*, November 15, 1884.

A Liniment for Earache.—Dr. Carlos Pavesi recommends a liniment composed of camphorated chloral, 2½ parts, pure glycerine, 16½ parts, and oil of sweet almonds, 10 parts. This is to be well mixed and preserved in an hermetically closed bottle. A pledget of very soft cotton is to be soaked in the liniment and then introduced as far as possible into the affected ear, two applications being made daily. Frictions may also be made each day with the preparation behind the ear. It is claimed that the pain is almost immediately relieved, and even in many cases the inflammation is subdued.—*El Sentido Católico en las Ciencias Médicas.*

Collodion in the Chest Pains in Phthisis.—Dr. Rigaud believes that the intercostal muscles, as well as the nerves, are the seat of the severe pains so often experienced during the course of phthisis. The pain caused by deep inspiration or a paroxysm of coughing is very different from the intercostal neuralgia of beginning tuberculosis. For the relief of these pains the author recommends painting the affected side of the chest with a thick layer of collodion in order to immobilize it as far as possible. In a number of cases in which this was tried in the Hôpital Laennec it was very successful. A writer in the *Norsk Magazin for Laegevidenskaben* states that it has been tried extensively in the Rigshospital, in some cases with relief to the pain, but in the majority with but indifferent success.

THE MEDICAL RECORD:

CONGRESS AND CHOLERA.

As the short session of Congress rapidly wanes, it becomes apparent that there will be no new health legislation. The Bill of the Conference of State Boards of Health lingers in the Committee on Public Health, and is the subject of much criticism by sanitarians in different parts of the country. To add to the complication of affairs, a new health bill has been presented in the Senate, of formidable proportions, which it would require a long session of Congress to reduce to any practicable form. Both bills are very crude, and require, as they would receive before their passage by either House, a large amount of consideration and discussion. It is idle, therefore, for the country to expect any such legislation as these bills contemplate. Meantime, the known existence of cholera in European capitals, and the approach of spring, are beginning to excite popular alarm among all classes. And well it may, if we are to estimate our liability to an invasion of that pestilence by its past history, and the measures thus far adopted to prevent its introduction into this country. At the present time mere distance does not protect us from cholera. That disease in Paris threatens us as much as it does London. Indeed, it is probable that, considering the immense number of poor people who are constantly *en route* from all quarters of Europe to this country with their household goods in hand, New York is quite as much exposed to cholera as any continental city. Therefore the question now earnestly asked by citizens, is pertinent, and demands an answer, viz., Can anything be done to prevent the introduction of this epidemic into the United States? In our opinion, as we have before stated, this is a question which should be pressed upon every member of Congress. In view of the failure of general health legislation the question recurs, What is most practicable?

To us the solution of the problem is self-evident. Cholera must be warded off with the means at the command of the Government, without further delay for the action of Congress creating a new Board of Health. There is now no hope of such action, and, even if there was, we are very doubtful whether there would or could be any improvement upon the present organization. However that may be, it is plainly the part of wisdom for Congress and the Government to utilize every available resource at hand in averting a cholera epidemic. Believing, as we do, in the efficacy of proper preventive measures, intelligently executed by Government, we do not hesitate to affirm that, if the present National Board of Health were clothed with adequate powers, it could prevent the introduction of foreign pestilences into our seaports. Nor would the judicious exercise of such powers materially interfere with the travelling public, nor with commerce. Cholera is not an epidemic, in the ancient sense, which falls upon the people from the clouds or skies, but is a portable entity which must be carried from place to place by persons or luggage. As the Customs' officer knows well how to intercept those articles of commerce which are endeavoring to evade duties, so the qualified health officer can intercept the cholera contagion. With cholera three thousand miles away, and approaching us only along the great thoroughfares of commerce, it would not be difficult at once to inaugurate *a system of sanitary inspection* of travellers and luggage along those routes, which would effectually prevent the germs of the scourge from reaching the mainland.

What, then, are difficulties in the way of the immediate organization of preventive measures and their execution by governmental authority? Nothing whatever but conferring suitable powers upon, and the appropriation of adequate means to, the present constituted authority. Here is a National Board of Health, already organized and prepared to perform the very duties required by the present emergency. This board has in the past proved itself fully competent to meet and determine all health questions, and to execute all needful sanitary duties. In its organization it has all the efficiency of a single officer, with the advice and counsel of four expert sanitary officers. Why, then, should Congress waste precious time in endeavoring to create a new board? Must pressing sanitary duties, like those now awaiting the action of Congress, be fatally postponed while it considers the crude and ill-digested bills which will daily accummulate in its committees? We trust not. Congress should at once confer on the present National Board of Health adequate powers and authority, and provide it with ample means to enforce all necessary measures of prevention. There is no time to be lost if any steps are to be taken by the general Government to prevent the introduction of cholera into the United States during the coming season. The National Board should meet at once, and continue in session until all of its plans of operation are fully matured. The Public Health Committees of both Houses of Congress, instead of wasting time and effort in considering the wholly irrelevant matter of forming a new Board of Health, should be in daily communication and consultation with the present board in advising and perfecting measures which may require the action of Congress.

In the preceding suggestions and reflections we may seem to be unnecessarily anxious about the adoption and enforcement of preventive measures against cholera by the Government, but we are not, as time will prove. We have strong and positive convictions of the power of modern sanitary science, when intelligently applied, to control perfectly the diffusion of portable contagion. Full in this faith and conviction, we do not doubt that, if Congress would at once fully equip the present Board of Health, and if that body should at once meet and organize its methods of procedure and begin their execu-

tion, we should be saved a widespread epidemic of cholera with all its attendant loss of business and of life. Failing in such preparation, cholera is inevitable, and on Congress must rest the responsibility of a national visitation of the cholera-pestilence.

THE LATEST STAGE OF THE CHOLERA BACILLUS QUESTION.

THE preliminary report of Drs. Klein and Gibbes, regarding their investigations into cholera, carried on at Bombay and Calcutta, has been published in the *Gazette of India*, and is as follows:

"1. The statement of Koch, that 'comma-bacilli' are present only in the intestines of persons suffering from, or dead of, cholera, is not in accordance with the facts, since 'comma-bacilli' occur also in other diseases of the intestines, for example, epidemic diarrhœa, dysentery, and in intestinal catarrh associated with phthisis.

"2. The 'comma-bacilli,' in acute typical cases of cholera, are by no means present in such numbers and with such frequency as to justify Koch's statement that 'the ileum contains almost a pure cultivation of comma-bacilli.'

"3. The 'comma-bacilli' are not present in the tissue of the intestine or elsewhere.

"4. The 'comma-bacilli,' in artificial cultivations carried out by one of us (E. K.), do not behave in any way differently from other putrefactive organisms.

"5. Mucus-flakes of the ileum, taken out soon after death from typical acute cholera, contain numerous mucus-corpuscles, many of them filled with peculiar minute straight bacilli. The same bacilli occur also outside the mucus-corpuscles. They are never missed, even when the 'comma-bacilli' are.

"6. These small bacilli have been cultivated by one of us (E. K.), and they do not behave differently from putrefactive organisms.

"These small bacilli are not present in the tissues of the intestine or any other tissue.

"7. No bacteria of any kind, and no organisms of known form and character, occur in the blood or any other tissue.

"8. A good many experiments have been carried out by one of us (E. K.), with the following results:

"(*a*) Mice, rats, cats, and monkeys were fed with rice-water stools, with vomit, with mucus-flakes of the ileum, fresh and after having been kept from twenty four to forty-eight hours. The animals remained normal.

"(*b*) Inoculations with recent and old cultivations of 'comma-bacilli,' and the small straight bacilli, as well as with mucus-flakes, were made into the subcutaneous tissue, into the peritoneal cavity, into the jugular vein, and into the cavity of the small and large intestine of rabbits, cats, and monkeys; but the animals remained perfectly well and normal.

"9. The material which we have had hitherto at our disposal has been very good and abundant; and, as far as the microscopic work goes, we do not think we shall require any more material.

"We therefore propose concluding our inquiry by the beginning of December, and hope soon after to return to England."

The above report, being only one of conclusions without the data on which they are based, cannot be criticised at present. It is, however, unquestionably the severest blow against the comma-cholera-bacillus which has yet been struck.

The points made by Klein and Gibbes are that the Koch cholera bacillus is neither the specific organism of Asiatic cholera, nor is it practically of any diagnostic importance. It remains to be seen, however, whether they have proved, by cultures, the identity of dysenteric and other bacilli with those of cholera. It is to be remembered also, that a single positive inoculation experiment is more valuable than all the negative evidence; and it must be proved by Klein and Gibbes that the inoculations of pure cultures by Koch, and by Nicati and Rietsch did not, as claimed, produce genuine cholera.

We regret to observe that the question as to the existence of a cholera bacillus is becoming latterly one more of politics than science. A foolish and ill-advised letter, written by Professor Ray Lankester (who is no expert on such matters) to a London daily, charged Koch with having gone to India under a pressure to find a bacillus. This view seems to have been taken up by the English papers, and some of our New York dailies have obediently followed them.

AN AMERICAN TREATMENT OF ACUTE CROUPOUS PNEUMONIA.

So much criticism has been occasioned by our calling attention to the "American method" of using iodide of potassium in syphilis, that we have hesitated to apply any national qualification to a method of giving calomel in pneumonia, now employed by physicians in New York and perhaps elsewhere. It is, however, well known here that a considerable number of our physicians in large practice have for a long time been using calomel in enormous doses (gr. xx., gr. xxx., ʒ j.) in acute lobar pneumonia. These amounts are given, we believe, not always at the outset, but often in the second stage, with the view of checking the progress of the disease and promoting rapid resolution. Very positive views exist as to the frequent and marvellous efficacy of this treatment.

Calomel is one of the drugs which of late years has almost lost its place in the therapeutics of pneumonia. In most text-books it is either not referred to at all or is passed over with words of condemnation. In the English collective investigation of acute pneumonia, only ten among over a thousand reported using calomel in the disease.

Its great utility in large doses in acute pneumonia, however, was claimed by Hamilton in the latter part of the last century. Later it was recommended by Vogel, and in 1837 by Gobée. The last named author gave from gr. viii. to gr. xxiii. in twenty-four hours, but the administration of the medicine was preceded in his practice, as well as in that of his predecessors, by bleeding and tartar emetic. Dr. Graves, in his "System of Clinical Medicine," 1843, strongly recommends a speedy mercurialization at the onset of acute inflammation, and Dr. G. P. Cammann of this city, thirty years ago, used large doses of calomel in acute pneumonia. In this city, of late years, it is Dr. James R. Leaming, if we mistake not, who has

employed and advocated the heroic, or as they are sometimes called, the sedative doses of calomel in acute lobar pneumonia. A chapter on the "Therapeusis of Mercury" in his work on "Diseases of the Heart and Lungs," contains some most glowing eulogiums upon the drug in question, which to his mind contains a therapeutic potentiality beyond the dreams of wildest hope. Speaking of sedative doses of calomel in pleuro-pneumonia, he says that this disease is in some cases controllable only by that agency, "which is the shears that may clip the locks of the destructive Samson, and render it a mild disease." He adds later the curious statement that "it is not absorbed. It acts upon the organic life of the body, and may strengthen the heart's action, lower the temperature a few minutes after being placed upon the tongue!" . . . "Placed dry upon the tongue of the patient, like the touch of the wand of the magician, it instantly changes the conditions of life to those of death." These statements appear somewhat rhapsodical, but they come from an experienced and esteemed physician, and we are aware that others share more or less his view and follow his practice.

Heroic or "sedative" doses of calomel have been shown by Dr. Putnam-Jacobi, the late Dr. Lente, and others, to have apparently, at times, a powerful and beneficial effect upon the course of acute disease. For this, and on account of the testimony above referred to, it seems to be a matter of importance that the profession learn more regarding the reputed high value of this agent in acute pneumonia. We believe that, at present at least, the use of sedative doses of calomel in croupous pneumonia is a distinctively American practice.

QUACKERY AND MEDICAL WOMEN.

THERE are some indications that the sentiment in favor of the medical education of women has swung over almost too far, and that those ambitious to become lady medicals are in some quarters getting an amount of encouragement and pushing which is neither healthful nor just. Lately, we have beheld again the spectacle of a venerable medical institution assailed because it refuses to accept women as students. We believe that when a woman feels strongly and imperatively that she has the capacity to do a physician's work, good opportunities for her instruction should be offered. Such opportunities do now most abundantly exist, and, in general, peace reigns.

But we have been pained to notice that the women who take advantage of the present numerous and easy avenues into the medical profession are not, in a large proportion of cases, of the kind likely to reflect credit upon our art or do any service to society. We are quite safe in saying that a considerable minority of present medical women are quacks, that there is a great proportional tendency to seek irregular schools and adopt irregular professional methods. Looking over the personal medical advertisements in the public press, we have been surprised at the frequent appearance of advertising medical women.

There are at present, in the United States and Canada, seven medical colleges for women only, of which two are homœopathic, being a ratio of 2 to 5. Among the other colleges, the ratio of homœopathic to regular schools is as 1 to 8. A number of medical colleges now admit women as well as men. The total number of these in the United States is 35, out of a total number of 119 medical colleges. Of these 35, 7 are homœopathic, 7 eclectic, and 2 are "physio-medical," making a total of 16, against the remaining 19, which are regular schools. There are, therefore, in the United States, 23 regular schools and 18 non-regular, in which women are taught to be doctors. Apart from this statistical evidence, we have obtained information from various sources which leads us to the conclusion that the majority of women now wishing to be doctors go where they can get through easily, or where they will be taught a pseudo-science, or something worse. In our own city we observe that the Homœopathic Medical College for Women, which has a cheaper and shorter course, graduates a larger class than the regular medical college, although the latter's teaching advantages are unquestionably much superior.

These facts are certainly significant, and we have deemed it our duty to call the attention of educators and the profession to them; for it appears beyond question that the undue and indiscriminate encouragement of the medical education of women is really adding disproportionately and dangerously to the number of quacks and incompetent practitioners.

A HOSPITAL FOR SHOP-GIRLS.

A MOVEMENT is on foot to establish a hospital for shop-girls who have become ill and worn-out by work. Such a special institution would be very expensive, and is quite uncalled for. Already we have some twenty or thirty hospitals in the city providing for all forms of bodily affliction. The wiser plan would be to provide endowed wards for shop-girls in existing hospitals, if it is really found that this particular class is in more need than others of special hospital provision. Evening dispensaries might also furnish some help. But, most of all, a society which would teach shop girls to lead healthful lives, to avoid caramels, late hours, and fancy balls, would be of especial service.

Employers have their duties also in the case, but that particular question has already been freely discussed in these columns.

THE PROPOSED REMOVAL OF DARTMOUTH MEDICAL COLLEGE.

WE learn that an effort is being made to remove Dartmouth Medical College, otherwise known as the New Hampshire Medical Institute, from Hanover, where the college is situated, to Concord, N. H.

It is claimed by those interested in securing this removal, that the conditions upon which the Professors of the New Hampshire Medical Institution became, by act of the Legislature, December 15, 1824, Trustees of the State property at Hanover, consisting of one acre of land and a building used by that institution, have not been complied with. They also allege that there is quite a general feeling that the property should not be used by men who discriminate against women as medical students.

Naturally also, the argument is offered that a medical school should be moved to a place where greater clinical facilities exist than are possible in a town of twelve hundred inhabitants.

Apart from any technical considerations, the proposition to remove the college to Concord appears to be unwise, if not absolutely suicidal. According to the report of the New Hampshire State Medical Society's delegates, the college at its last Commencement graduated its largest class, and was in a most prosperous condition. During a period of ninety years it has sustained an excellent reputation as a teaching school. Its graduates should not in these days be content with its didactic lessons; but how much more could be learned in Concord, a city of fourteen thousand inhabitants? If any removal is contemplated, for clinical reasons, Manchester, a city twice the size of Concord, would seem to be preferable. But the fact is that no new medical school is needed or could thrive within one or two hours distance from Boston.

News of the Week.

Northwestern Medical and Surgical Society.—The fifteenth anniversary of this Society was celebrated on the 14th inst., by a dinner and reception at the Buckingham Hotel. A new departure was made from the usual "stag" dinner by the presence of the wives and lady friends of the members and other invited guests. The dinner was presided over by Dr. T. H. Burchard, and there were covers for seventy persons. Aside from the usual commemorative toasts, the Hon. G. H. Yeaman pleaded for the legal fraternity, and the shortcomings of the clergy were atoned for by the Rev. Dr. Lloyd. A humorous poem and several musical recitations were excellently given by some of the ladies. Altogether the occasion was a very happy one, and the Society is to be congratulated on the new social feature introduced at this, their first anniversary dinner.

New York Academy of Medicine: Election of Officers.—At the annual meeting, held January 15th, the following officers were elected: Dr. A. Jacobi, President; Dr. C. C. Lee, Vice-President; Dr. L. Elsberg, Corresponding Secretary; Dr. A. L. Loomis, Trustee; Dr. A. S. Hunter, Member of Committee on Admission; Dr. F. R. Sturgis, Member of Committee on Medical Education; Dr. A. H. Smith, Member of Committee on Ethics; Dr. E. D. Hudson, Member of Committee on Library.

Hospitals for Saleswomen.—With reference to this subject, which we have discussed elsewhere, we learn that a project is on foot for a fair to raise money for hospital beds for saleswomen.

The Value of Expert Testimony.—Medical expert (on the witness stand): "No, sir, it would have been impossible for the accused to quietly think out his plans for committing the murder while walking on Broadway." Counsel for the defendant: "State why, doctor." Medical expert: "Because Broadway is the main artery of the city, and my professional skill teaches me that a quiet vein of thought on a main artery is paradoxical and absurd."—*New York Times.*

Marion County (Indianapolis) Academy of Medicine.—At the regular meeting of the Marion County (Indianapolis) Academy of Medicine, January 6, 1885, the following officers were elected for the ensuing year: Dr. Thomas N. Bryan, President; Dr. A. W. Brayton, Vice-President; Dr. F. W. Ferris, Secretary; Dr. J. O. Stillson, Assistant Secretary; Drs. T. B. Harvey, F. S. Newcomer, L. L. Todd, E. Hadley, G. V. Woolew, George Cook, Censors.

A Contest over the Will of the Late Professor William Darling is expected. A will, dated April 27, 1881, leaves the property to Amelia Delacroix, of Yonkers, "an esteemed and valued friend." A second will, it is claimed, was made on June 25, 1883, leaving the property (or part of it) to the New York University Medical College. A third claimant is a Mrs. Catherine Lefferts, who asserts that Professor Darling was at one time married and had children, of whom she was one. A fourth claimant is Mr. John Darling, of Burlington, Iowa, an alleged brother.

The Utica Asylum, which has been in a state of chronic investigation for many years, is having a short recess owing to a legal technicality, which prevents the getting a quorum of the managers.

The Hospital Contributions for 1885.—At the annual meeting of the Hospital Saturday and Sunday Association, on January 19th, the Treasurer reported that collections for the year had so far amounted to $30,988.90, and that enough more had been promised to insure a total of at least $36,000 by the end of this month. Of the above sum about $7,300 is specially "designated." Of this, St. Luke's Hospital gets $3,184, the Presbyterian, $1,589, and St. Mary's, $1,227. Last year the sum collected amounted to $43,062.74. The falling off was in the collections at the churches, presumably because Hospital Sunday was rainy. The trade auxiliary associations, on the other hand, have done better than ever. The dry goods men gave $4,118.10, against $3,933.06 last year; tobacco dealers, $2,000, against $1,734.90 last year; the clothing trade, breweries, and insurance men, $300 each. There have also been contributions from various lodges and from printers. The following officers were elected for the ensuing year: George Macculloch Miller, President; Hyman Blum, Vice-President; Charles Lanier, Treasurer; Rev. George S. Baker, Corresponding Secretary; John S. Bussing, Recording Secretary. Various committees were also appointed.

Dr. Charles W. Shumway died at his residence, Chicago, on January 18th, at the age of fifty-eight. He was a graduate of the College of Physicians and Surgeons of New York.

Another American Fellow of the Royal College of Surgeons.—Dr. W. P. Manton, of Detroit, Mich., writes that the late Professor Darling was not, as was stated in his obituary notice, the only F. R. C. S. in the United States. Dr. W. B. Platt, of Baltimore, Md., received this degree in 1883.

Professor Theo. Meynert, of Vienna, on account of his distinguished services to science, has been given the title of Hofrath.

Dr. Rudolf Tauszky.—This unfortunate physician has quite recovered from the wound which he inflicted upon himself, but he is insane, and, it is feared, hopelessly so.

Dr. James Dunn, one of the prominent physicians of Virginia, died in Petersburg, January 19th, after a lingering illness, aged fifty-four years. During the late war he was one of the leading surgeons in the Confederate Army.

The Missouri State Board of Health and the Medical Practice Act has recently been sustained by a decision of the Supreme Court. The Board can, therefore, refuse to grant licenses to practise to quacks or graduates from irregular and inferior schools.

The Annual Prize of $50, offered by the Baltimore Academy of Medicine for the best thesis read by a member during the year, has been given to Dr. John N. Mackenzie. Dr. Mackenzie's paper was read before the Academy on January 15, 1884, and was entitled, "Irritation of the Sexual Apparatus as an Etiological Factor in the Production of Nasal Disease."

The First Horse Ambulance Service on the Continent has, through the influence of Dr. B. Howard, been adopted by the Municipality of Toulouse, where its working is greatly appreciated by all classes.

Civil Service Reform and Medical Appointments.—A competitive examination to fill future vacancies in the medical departments connected with the City Government, as prescribed under the laws of the State of New York relating to appointments under Civil Service, will be held on Monday, February 2, 1885, at such time and place as will be announced in the city papers of the preceding Saturday. The necessary application papers may be obtained of Russell Sturgis, Esq., 23 East Twentieth Street, New York. Applicants must be regular graduates in medicine and residents of this city.

T. H. Burchard, M.D.,
Thomas H. Manley, M.D.,
J. Tilden Brown, M.D.,
Examining Board.

A Sanitary Protective League has been organized in this city. Its object is to unite, if possible, all existing sanitary societies in a league to protect the city against cholera. There are several such societies, including the Ladies' Health Protective Association, the Hebrew Sanitary Society, the New York Association for Improving the Condition of the Poor, which has a Sanitary Committee, and the State Charities Aid Association. It is proposed to group all the members together, and then divide them up into local committees, whose duty it will be to report to a general committee any facts which may come to their knowledge regarding sanitary defects. The Sanitary Auxiliary Society of New Orleans, according to Mr. C. F. Wingate, has kept yellow fever out of that city for four years by just such a system as this that is proposed, and there is the best of ground to hope that the league can succeed in preventing a cholera epidemic here. The plan of the Sanitary Protective League also contemplates personal investigations by the general committee of all markets, dairies, sources of milk supply and food, and everything in its power to assist the authorities of the Health Board. Sanitary tracts on cholera will be published and circulated throughout the city free, and all information available will be given to the public in regard to cholera and the best means to prevent it. As soon as the organization has been completed a public meeting will be held in Chickering Hall, for discussion of the subject of cholera.

The Archives of Medicine.—We regret to learn that the publication of this valuable journal has been suspended. The editor says in his announcement that "The experience of the past year has convinced him that the verdict of the times is in favor of periodicals appearing at brief intervals, able to furnish scientific material and news with the utmost promptness and in a fresh state. These considerations affect contributors and subscribers alike, and contribute to the preference for weekly issues."

The New York State Medical Society—Fare to Albany.—Dr. C. L. Dana, Secretary of the County Delegation, writes us that round-trip tickets from this city to Albany can be purchased of the West Shore Railroad Co. for $3.10. On Monday afternoon, February 2d, a train with an extra palace car leaves from the down-town station at 3.50 P.M., from Forty-second Street station at 4 P.M., arriving in Albany at 9.10 P.M.

Bogus Medical Diplomas.—Dr. John Buchanan, who became notorious three years ago by issuing bogus medical diplomas, was again arrested in Philadelphia on January 20th, together with a woman calling herself Dr. Rebecca Russell, who claims to be Buchanan's business partner. Buchanan is charged with having again issued bogus diplomas since his release from prison, and further with forgery, in having subscribed the names of some of Philadelphia's most prominent physicians to his bogus sheep-skins in order to enhance their value.

A New Cancer Cure.—Washington, D. C., seems to be the fostering mother of cancer cures. The latest is a Brazilian plant, called *alveloz*, and belonging, it is said, to the family of Euphorbiaceæ. Last September the United States Consul at Pernambuco wrote a letter to the State Department, inclosing a report by Dr. R. Bandeira, surgeon at the Pedro Hospital at Pernambuco, regarding a cancer cure to which wonderful properties were ascribed. A magistrate, Dr. Guemres, was the first that made it known, four years ago. He had a cancer of the face. He was perfectly cured there by the natives of the country, using this remedy, and he wrote to Recife, sending the plant and its juice, which was tried, Dr. Bandeira says, with success in several cases. Last year the juice of *alveloz* was used in the Hospital Pedro with such success that Dr. Vellozo published a notice in the papers advising the employment of it. Many other experiments have been made in cases of epithelioma of the lips, nose, face, and eyelids. The application of *alveloz* in sarcoma or carcinoma, has not given the result that many hoped, and it appears that the efficacy of the new drug is limited to epithelioma.

Reported Appearance of Cholera in St. Louis.—Two persons are reported to have died of cholera this week in St. Louis. It is not possible to say as yet that these were cases of genuine epidemic cholera. It is greatly to be regretted that our health authorities still have no experts qualified to interpret the significance of the bacilli found in alleged cholera cases.

Reviews and Notices.

THE INTERNATIONAL ENCYCLOPÆDIA OF SURGERY: A SYSTEMATIC TREATISE ON THE THEORY AND PRACTICE OF SURGERY. By authors of various nations. Edited by JOHN ASHHURST, JR., M.D., Professor of Clinical Surgery in the University of Pennsylvania. Illustrated with chromo-lithographs and wood-cuts. In six volumes. Vol. V. New York: W. Wood & Co. 1884.

A new volume of this great work is now before us, and like its predecessors reflects credit upon all engaged in its production. This, the fifth volume, continues the detailed discussion of regional surgery. Injuries of the head are considered by Dr. Nancrede of Philadelphia, who handles his subject with thoroughness and skill.

Dr. Frederick Treves, of London, favorably known on both sides of the Atlantic, is the author of a comprehensive and thoroughly practical exposition of the malformations and diseases of the head.

The next chapter is written by Dr. E. Williams, of Cincinnati, and embraces a consideration of the injuries and diseases of the eyes and their appendages. In a work of this kind it was hardly necessary to introduce a section on the anatomy of the eye, but aside from this criticism, we can only commend the article as an able and trustworthy presentation of a difficult subject.

In the following chapter Dr. Albert H. Buck discusses, in a very satisfactory manner, the injuries and diseases of the ear. The nose and its accessory sinuses is similarly dealt with by Dr. George M. Lefferts. Then comes an elaborate article on injuries and diseases of the face, cheeks, and lips, contributed by Dr. A. C. Post.

Christopher Heath ably discusses the surgery of the mouth, fauces, tongue, palate, and jaws. He is followed by Dr. Kingsley, of New York, who takes up the surgery of the teeth and adjacent parts. Injuries and diseases of the neck are admirably described by Dr. Macleod, of Glasgow. The article by Dr. Solis-Cohen, of Philadelphia, on the air-passages is a very complete and practical one, and, although it seems rather lengthy, it is never prolix in unnecessary details. The chest and breast follow, the former article being prepared by Dr. Bennett, of Dublin, and the latter by Thomas Annandale, of Edinburgh. Especially the last-named article shows a masterly grasp of subject, and bespeaks the careful surgeon, the conscientious observer, and lucid writer. The injuries and diseases of the abdomen have been assigned to Dr. Henry Morris, of London, who, in an article replete with exact information, shows how a difficult subject may be made clear by skilful and systematic handling.

The concluding article on hernia is from the pen of Dr. John Wood, of London, who does ample justice to a most important subject that has a constant interest for physicians as well as surgeons. That portion of his essay dealing with the construction and application of trusses might have been made still more useful by the incorporation of more detailed accounts of the most modern modifications of apparatus of that kind.

Taken all in all, there is scarcely any room for fault-finding with this volume, and it will take its place alongside of its predecessors, adding its full measure toward the success of the encyclopædia.

A PRACTICAL TREATISE ON THE DISEASES OF THE EAR, including a Sketch of Aural Anatomy and Physiology. By D. B. ST. JOHN ROOSA, M.D., LL.D. Sixth edition. Revised and enlarged. Pp., 718. New York: William Wood & Co. 1885.

IF any one thing more than another attests to the value of a scientific text-book, it is the rapid succession of its editions. Scarcely two years pass, when a new issue of this valuable work is announced, the first having appeared in 1873.

The present work emphasizes the well-known views of the author in the more ordinary fields of aural practice, as deduced from his own large experience; while a liberal spirit is shown on those points open to a variety of opinion. The work is fully up to the times, and proclaims no new school of otology; in this sense it is thoroughly practical, and deserves the generous reception accorded to it by the medical profession and a scientific reading public.

After forty pages of a valuable *résumé* of otological literature, Dr. Roosa finds no ground for giving the syringe other than first place in the removal of foreign bodies from the ear: exceptional cases demand exceptional methods. He reasserts his belief as to quinine-salts; that they "produce congestion of the labyrinth and tympanum, and sometimes distinct inflammation, with permanent tissue changes."

The pathology of deafness after mumps is still *sub judice*, and will probably so continue, until a larger percentum of cases is quoted than that noted by the author, viz., one in five hundred cases of aural disease. Ten cases are detailed with manifest middle-ear complication.

Dr. Roosa coincides with the experiences of well-known otologists as to the negative results of every form of electricity in deafness of the internal ears. We are glad to see that he deprecates the use of the name, "Ménière's disease," when writing on syphilitic affection of the cochlea; as also that he reports so many cases of recovery of hearing by anti-syphilitic treatment, with which some recently published experiences seem to be at variance. The author's recent papers on the value of the tuning-fork in differentiating between diseases of the middle or internal ear are still fresh, and we quote his conclusion: "If, in cases of impaired hearing, aërial conduction (with the tuning-fork) be better and longer than bone-conduction, we have disease of the internal ear. If bone-conduction be better than aërial, there is disease of the middle or external ear."

The chapter on acute suppuration of the middle ear should be read by every practitioner of medicine. A careful perusal of an aggravated case of middle-ear disease, given on pp. 321–331, is worth the price of the book to any one treating ear patients. An acute otitis media with pain in the mastoid and side of the neck, simulating retained pus, eventuates in a true neurosis of the middle ear.

Generous doses of milk, whiskey, and quinia, advised by a well-known general practitioner, struck the key-note of treatment. The author states that the early paracentesis of the drum-head, and the later Wilde's incision, were not only unnecessary, but that they aggravated the case. How much worse would have been trephining the mastoid, advised by one consultant! While the author does not any less disapprove of Von Fröltsch's position that, "inflammation of the tympanic cavity is essentially a periostitis," yet he desires to emphasize the neurotic complications in a case debilitated, as was this, by any one or more causes of anæmia; such as overwork, anxiety, or malaria. Dr. Roosa states, on the one hand, the consequences of a neglected aural catarrh; while, on the other, he greatly inveighs against maltreatment of an acute suppuration.

The publishers have done their part well, as to excellence of anatomical sketches, display of instruments, and large type.

LE CHOLÉRA DANS LA BASSE-EGYPTE EN 1883. Par le DOCTEUR DUTRIEUX-BEY. 8vo, pp. 287. Paris: O. Berthier. 1884. THE CHOLERA IN LOWER EGYPT. By DR. DUTRIEUX-BEY.

THE author, who is honorary professor in the Medical School of Cairo, gives a history of the cholera epidemic in Egypt last year, with practical conclusions from his personal studies. His last sentence deserves to be quoted; it is "*Tout à l'hygiène!*"

A Theoretical and Practical Treatise on the Hemorrhoidal Disease: Giving its History, Nature, Causes, Pathology, Diagnosis, and Treatment. By William Bodenhamer, A.M., M.D. Illustrated by two chromo-lithographic plates and thirty-one wood-cuts. New York: W. Wood & Co. 1884.

The author of this comprehensive monograph is already favorably known as a writer in the department of practice of which it treats. Several of the articles contained in the volume before us will be recognized by the readers of The Record as having appeared in its columns. Hemorrhoids are of such frequent occurrence, and often prove almost as troublesome to the practitioner who attempts their cure, as to the patient who seeks relief from his sufferings.

Dr. Bodenhamer's treatment of hemorrhoids is simple and rational. His treatise will be welcomed by the profession as a complete and satisfactory one of its kind.

A Handbook of Ophthalmic Science and Practice. By Henry E. Juler, F.R.C.S., Junior Ophthalmic Surgeon to St. Mary's Hospital, Senior Assistant Surgeon and Pathologist to the Royal Westminster Ophthalmic Hospital, formerly Clinical Assistant at the Royal London Ophthalmic Hospital, Moorfields. With illustrations. 8vo, pp. 416. London: Smith, Elder & Co., 15 Waterloo Place. 1884.

The contents of this book are presented in a sequence of ocular diseases, beginning with those of the lids, lachrymal apparatus, conjunctiva, cornea, sclerotic, iris, ciliary body, choroid, optic nerve, and retina, and ending with disturbances of the lens and visual field, amblyopia, errors of refraction, etc., the latter category occupying more than two-thirds of the work.

Under the head of lid-operations, Wolfe's transportation of skin *en masse* is given prominence over other means of correcting deformities of these parts. The author, however, prefers skin-grafting to this and older methods. The late Mr. Critchett's operation of pericorneal section of a bridge of conjunctiva is given preference in all operative means for the relief of pannus, while the use of jequirity, now quite general, is described, though not warmly advocated. Inoculation with pus is given its true position in the treatment of such cases; it should be used only as a last resort.

The pages devoted to the visual field and to the use of the perimeter in detecting the limited excursions of the field in the various forms of toxic amaurosis; the chapter on color-blindness (achromatopsia), and the elaboration of Holmgren's tests in the railway and marine service; the interesting pages upon hemiopia and its presumable lesion in the occipital lobes and angular gyrus will specially commend themselves to the accurate student of ophthalmology. They are written from a genuine clinical basis, while at the same time they premise an understanding of the physical and physiological factors, so far as these are known. Under the head of amblyopia or amaurosis, the reviewer fails to find any reference to the interesting group of ocular symptoms in the later months of pregnancy; while, on the other hand, malingering, or simulated amblyopia, properly receives large attention from the author. McHardy's new perimeter for mapping out the fundus of the eye is perhaps no better than Forster's, so long in use, but its mechanism is easier and more ingenious.

The author's ophthalmoscope is shown in full size in woodcut; it contains two discs of spherical lenses, one convex, with ten, and one concave, with eleven lenses, and a revolving sector with four lenses and an aperture. A similar instrument has long been in use in this country, and of much lighter build. The pages devoted to testing errors of refraction by the ophthalmoscope are well written, and the method, known as Retinoscopy, or the Shadow-Test, is of especial interest. On page 377 two examples of fitting presbyopic glasses to a far-sighted and a near-sighted patient are given, in which the corrections for age are given much higher than in Donders' tables.

The colored plates and woodcuts are taken from cases in the large hospital services of the author and his colleague, Mr. Anderson Critchett, who was for many years associated with the elder Critchett. The plates of corneal neoplasms and of pathological processes in the iris, choroid, and retina are unusually good.

There are fewer errors than usual in the text and index, and the publishers' work is well done.

Diseases of the Nose. By Clinton Wagner, M.D., Professor of the Diseases of the Nose and Throat in the New York Post-Graduate Medical School, etc. New York: Bermingham & Co. 1884.

The rhinoscopic era in medicine has brought with it a mass of special literature that at times threatens to overwhelm the practitioner. Nevertheless, after perusal of Wagner's little treatise, we are forced to conclude that there was room for one more good book on the diseases of the nose. The work is not intended for specialists, but seems eminently suited to teach the physician in general practice enough about rhinology to enable him to deal more or less successfully with catarrhs, nasal polypi, and other growths, without the assistance of a specialist. A valuable feature of this book consists in a carefully selected bibliography appended to the text.

Diseases of the Spinal Cord. By Byron Bramwell, M.D., F.R.C.P. (Edinburgh), Pathologist to the Edinburgh Royal Infirmary, etc. With 183 illustrations. Second edition. Edinburgh: Young J. Pentland. 1884.

The first edition of this work appeared in 1882, and it has now been found necessary to issue a second. It certainly speaks well for the body of the medical profession that it so quickly recognizes a book of real value. We are informed by the author that his work has also been translated into German, French, and Russian. It is not an exhaustive treatise, but for a concise résumé of our actual knowledge concerning the diseases of the spinal cord it has no equal.

Pyuria; or, Pus in the Urine and its Treatment. Comprising the Diagnosis and Treatment of Acute and Chronic Urethritis, Prostatitis, Cystitis, and Pyelitis, with Especial Reference to their Local Treatment. By Dr. Robert Ultzmann, Professor of Genito-urinary Diseases in the Vienna Polyclinic. Translated, by permission, by Dr. W. P. Platt, F.R.C.S. (England), Demonstrator of Surgery in the University of Maryland, etc. New York: D. Appleton & Co. 1884.

This is rather a long title for a small volume of ninety-odd pages. But it appears, from a study of its contents, that the title is the least satisfactory part of the book. Ultzmann has for a number of years been favorably known as a specialist in the department of genito-urinary diseases. His modest little book is an earnest plea for local treatment based on exact differential diagnosis. The physician cannot fail to derive profit from a careful perusal of the author's therapeutic recommendations.

A Practical Treatise on Fractures and Dislocations. By Frank Hastings Hamilton, A.B., A.M., M.D., LL.D., late Professor of Surgery in Bellevue Hospital Medical College, Surgeon to Bellevue Hospital, New York, etc. Seventh American Edition, revised and improved. 8vo, pp. 1005. Philadelphia: Henry C. Lea's Son & Co. 1884.

There is no longer any necessity for reviewing this admirable work. It has triumphantly advanced to its seventh edition, its venerable and talented author still keeps abreast with the times, and it is still the most exhaustive practical treatise on fractures and dislocations in this or any other language.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, January 15, 1885.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

AFTER the reading of the minutes of the last meeting the following annual reports were presented:

REPORT OF THE COUNCIL.

The Council recommended that five hundred dollars be expended in subscriptions for medical journals. Adopted.

The Council further recommended that a sum not to exceed two thousand dollars be appropriated for the library. Adopted.

It further recommended that the thanks of the Academy be tendered to Dr. C. R. Agnew for his contribution of fifty dollars and services in securing the exemption of the property of the Academy from taxation; also that a vote of thanks be tendered to Messrs. Taft & Benedict, attorneys, for a contribution of one hundred and twenty-five dollars for the same purpose. Adopted.

REPORT OF THE TREASURER.

DR. W. F. CUSHMAN, Treasurer, presented his annual report, from which it appeared that there was a balance in the treasury of $1,880.47. It further appeared that, during the last year, contributions to the fund to liquidate the mortgage had reached the total amount of $1,880.

REPORT OF THE BOARD OF TRUSTEES.

This report showed that an effort had been made to tax the property of the Academy, from which an appeal was made by the Board of Trustees, and the case was taken before Judge Donohue, who directed the Comptroller to strike the assessment from the list. The Board further expressed the opinion that the question of taxation of the property of the Academy had been permanently settled.

It also appeared in the report that a sum of nearly, if not exceeding, one-half the amount necessary, had been secured by the new Committee on Ways and Means, for liquidating the present mortgage.

REPORT OF THE COMMITTEE ON LIBRARY.

The report showed that the library contains thirty-five thousand bound volumes and nine thousand pamphlets.

DR. JOHN C. PETERS further reported that in the routine of business as Librarian of this Academy, certain official communications had come to him from the librarian of the École de Médecine, of Paris, and also from the dean and permanent secretary of the Academy of Medicine of Paris. They were in acknowledgment of the receipt of regular exchanges of books and pamphlets between the New York Academy of Medicine and the learned bodies above mentioned, brought about by the President of the New York Academy of Medicine.

The first was from Dr. Béclard, Permanent Secretary of the Library of the Academy of Medicine, Paris, dated December 8, 1884, in which Dr. Barker was addressed as Mr. President and Honored Confrère.

Dr. Béclard, also Dean of the Faculty of Medicine, an institution entirely separate from the Library of the Paris Academy of Medicine, had instructed his colleague, Mr. Cheveau, Librarian of the Faculty of Medicine, to acknowledge the receipt of books, and spoke of Dr. Barker as most honored president and confrère, with the sentiments of highest esteem, addressing him as Dr. Fordyce Barker, President of the Academy of Medicine, New York.

Dr. Teed, of Kansas City, was introduced to the Academy and invited to a seat on the platform.

DEMONSTRATION OF KOCH'S CHOLERA BACILLUS.

DR. E. C. WENDT: "I have placed under the microscope a very perfect specimen of the cholera bacillus, which was kindly sent me by Robert Koch, of Berlin. He writes that it was prepared from a pure culture. It shows well the characteristic shape of the so-called comma-bacillus. Of course a simple demonstration of this kind proves nothing with regard to Koch's well-known doctrine, which assumes this bacillus to be the specific cause of Asiatic cholera. Nevertheless so much has been recently said and written about the comma-bacillus, that it may interest you to actually inspect its peculiar appearance. So far as I am aware this is, with the exception of a slide in the possession of Dr. Billings, the only authentic specimen now in America, and I take great pleasure in giving the members of the Academy an opportunity to examine it. One word more. You are doubtless all aware that chief among the objections to Koch's doctrine was the claim of Lewis, that comma-bacilli were normally present in the mouth and fauces. Under the second microscope I have placed a specimen, prepared by myself, from the buccal secretions of a healthy man. In addition to a great variety of bacteria, you will not fail to observe some curved bacilli. But on comparing them with those of cholera you will easily detect differences that I need not here enlarge upon. Quite apart from this point, however, it is well to bear in mind that identity of shape does not signify identity of morbid action. In conclusion let me say that, while the exact diagnostic significance of the cholera bacillus is still *sub judice*, the claims of Koch rest on so substantial a basis that it will require actual scientific proof, and not mere scepticism and denial, to overthrow them."

OBSTETRIC FORCEPS AND SPECULUM.

DR. W. B. SCHUYLER exhibited a new obstetric forceps, pointed out the advantages which it possessed, especially with reference to the arrangement of the shanks and curves. A complete description of the instrument, with its advantages and peculiarities, can be found in the *New York Medical Journal*, March 4, 1884.

The speculum was an ingenious combination of the Sims, Thomas, and Nott specula, and had also been described in the *New York Medical Journal* for September, 1876.

It was claimed for the instrument that it could be introduced easily, opened readily, and that it was self-sustaining.

DR. F. A. CASTLE directed attention to the fact that the intention of Dr. Nott, in devising his speculum, had been entirely subverted by the changes which the instrument-makers had from time to time made in the instrument, and that as it now appears it could scarcely be recognized as the original instrument.

DR. W. GILL WYLIE then read a paper (see p. 85) entitled,

DISEASES OF THE FALLOPIAN TUBES: THEIR RELATIONS TO UTERINE DISPLACEMENTS AND THE USE OF PESSARIES.

DR. E. NOEGGERATH was invited to open the discussion, and said that he had listened with a great deal of pleasure to the scientific and practical paper of the evening, and that while there were very many difficulties and a great variety of opinion concerning the investigation of this class of cases, he would only direct attention to a few points which were still the subject of discussion.

First, he would repeat what had already been stated at the International Medical Congress of Copenhagen, that it was a misnomer to call the operation "Tait's operation." Hegar, in September, 1879, reported forty-two cases in which this operation was performed, with or without the removal of the tubes and performed to meet the same indications. Therefore, if Tait was to receive any mention in connection with the operation, it should

be simply as to the number of cases in which he had operated.

Dr. Wylie had asked whether always in cases of salpingitis the disease was caused by gonorrhœa. Dr. Noeggerath had investigated this subject, and made special researches in this direction for the purpose of demonstrating the presence of the gonococcus. Now, the gonococcus is a diplococcus, and of these four different species had been described as existing in the vagina. As yet, however, we had not been able to obtain a gelatine in which the gonococcus could be cultivated. Dr. Noeggerath had already tried four different kinds of gelatine and had had not yet been satisfied with the results—the microbes obtained by culture did not resemble the original ones. He had also compounded a coloring material which stained the gonococcus a peculiar red color, and the other tissues of a different color, but he had failed in this respect, because, as he now believed, in the uterus after a certain time—say six, eight, or ten weeks—if there be gonococci they exist in such small numbers that the micro-organisms can be demonstrated only by culture in gelatine, which as yet he had not succeeded in doing.

He could not say, therefore, whether the secretion of gonorrhœa in its chronic state was simply the result of a paralytic condition of blood-vessels, originally produced by the gonococcus, or whether the gonococcus still existed in small quantities, producing emigration of leucocytes. The demonstration of the gonorrhœal origin rested as yet only upon clinical facts.

As to the connection between salpingitis, perimetritis, and uterine dislocation, if there was anything which was characteristic of salpingitis and perimetritis, it was lateral version combined with anteversion.

He did not doubt that Dr. Wylie had seen retroversion with pyosalpinx, as there were probably such severe cases, but they were the exceptions.

If there existed nothing else upon which to make a diagnosis of salpingitis, the fact that there was diminished mobility of the uterus, with anteversion, or with light lateral version, and a certain form of uterine catarrh, was sufficient. Furthermore, with regard to retroversion, he was well aware that, eight or ten years ago, a certain number of gynecologists were of the opinion that this dislocation, without the existence of adhesions, was a rarity. He did not, however, regard it as such, and believed that in ninety per cent. of cases of retroversion the uterus could be replaced and kept there, and that those cases in which it could not be replaced, in consequence of adhesions, were very rare.

With regard to the diagnosis of salpingitis, we had to divide the cases into two classes: first, ordinary salpingitis with slight exudation, and, second, the disease in its later stages, where we had pyo- or hydro-salpinx.

In the first instance it was not necessary at all to feel the tube, but if there was decided perimetritis, with catarrh, minute condylomata about the hymen and labia minora, and erosion around the orifice of the vulvo-vaginal glands, we knew that salpingitis existed, because the cases where perimetritis existed without salpingitis were so extremely rare that those cases in which it did not belonged to the exceptions.

In the second instance, the *shape* of the tumor was of great importance in diagnosis. The tumor in salpingitis was, as a rule, not a single one, but a tumor divided into two or three sections, and of the shape of a cone running in the direction of the lateral diameter of the pelvis. In very doubtful cases we could touch the tubes directly by the recto-vesical touch.

The large majority of cases of salpingitis were not ready for surgical operation, and the treatment in such cases was very much like that described by Dr. Wylie; but there was one mode of treatment which he had found most efficient of all, and that was the prolonged use of the waters of Franzensbad, in Bohemia.

Dr. A. J. C. Skene said, with reference to pathology, that he accepted the position taken by Dr. Noeggerath, and, so far as his observation went, it was rare to see disease of the Fallopian tubes without having been preceded by gonorrhœa. On the other hand, he was inclined to take issue with Dr. Noeggerath with regard to the rarity of the occurrence of pelvic peritonitis without disease of the Fallopian tubes, for he thought that such cases occurred not infrequently.

With reference to the question of diagnosis, Dr. Skene accepted what had been stated by Dr. Wylie and Dr. Noeggerath, but the practical difficulty seemed to be in distinguishing between simple ovarian cysts in the prolapsed condition and pyo- or hydro-salpinx; perhaps the difference was most marked with reference to hydro-salpinx. There was one point to which attention had not been directed, and that was differential diagnosis by aspiration. If it was true that ciliated epithelia were so generally present, what objection could there be to removing by aspiration a portion of fluid and examining it under the microscope? Out of twenty-one specimens which he had examined, ciliated epithelia had been found in eighteen, thus indicating the condition that was present.

This fact also raised a question with regard to treatment. If the operation for removal of the tubes could be avoided—an operation which, to his mind, was something of a fearful necessity—it was certainly a step which no one would hesitate to take. After aspiration, a hydro-salpinx might not refill, and the aspiration might be followed by recovery. If the diseased tube could be thoroughly evacuated, the chances were that the cases would terminate in recovery in many instances. He thought, therefore, it would be well, many times, to try aspiration more thoroughly than it had yet been tried, both as a means of diagnosis and as a means of treatment.

Dr. P. F. Mundé, since he had had opportunity to follow out Dr. Noeggerath's teachings, and since Tait had published his successes in operating, had investigated this class of cases with special reference to diagnosis, and it was yet the one point upon which he was not at all satisfied. Dr. Wylie had been unable to give any new information on this part of the subject, and Dr. Mundé thought it was impossible to make a diagnosis in the very cases in which it was most desirable. In cases of pyo- and hydro-salpinx, the diagnosis could be made either with the fingers or by the use of the aspirator. The cases in which diagnosis was most desirable were not those in which there was a soft sausage-like tumor that could be distinctly felt, but they were those where there existed a diffuse thickening or infiltration of the tissues in each side of the pelvis, in which the patient complained of pain upon pressure, and pain at irregular intervals, with, perhaps, discharges of small quantities of pus. It was in such instances that the diagnosis was most difficult, and in those cases Dr. Mundé believed that the only positive assurance on this point rested in exploratory incision.

Furthermore, he did not believe yet that laparotomy would be very frequently performed. So long as we have no means of making a clear diagnosis, the operation will not be as popular as could be wished.

With regard to the influence of inflammation of the tubes upon uterine displacements, he agreed with Dr. Noeggerath that lateral displacements were the most frequent, but he had seen retro-displacements after chronic salpingitis, and thought that while they were not as common as lateral, they were more frequent than anterior displacements.

Concerning adhesions, he agreed with Dr. Noeggerath, that in the majority of cases of retroversion the uterus was not adherent.

With reference to treatment other than by laparotomy, Dr. Mundé thought we were rather at loss, and that but little could be done. He had in some cases in which there was nothing but a diffuse swelling, seen more benefit follow the local application of the constant electric

current than from any other means, using from twelve to sixteen cells of the ordinary battery, with sittings of from fifteen to twenty minutes every day or every other day. The benefit which had followed this treatment, according to his experience, was not in the way of greatly diminishing the exudation, or in reducing the adhesions, but in allaying the pain. This, however, did not cure pyo-salpinx with distinctly diseased tubes.

From our present stand-point he thought that Dr. Wylie's paper had been so complete as to leave but very little to offer in the way of discussion.

Dr. Wylie felt satisfied that if Dr. Mundé would take the pains to adopt his method of preparatory treatment, in those cases in which there was a marked diffuse induration, with fulness in the iliac regions, the diagnosis would become quite easy. In his first cases he was in doubt, as was Dr. Mundé, but in his later cases he had, by the use of glycerine and alum applied on a thin pledget of cotton two or three times a week, been able to so reduce the thickening as to enable him by digital examination to diagnosticate the exact condition of affairs within the pelvis.

Dr. Wylie doubted if hydrosalpinx would be cured by aspiration. With reference to diagnosis by means of the aspirator, he thought that, as a rule, if there was a large tumor, either a dilated tube or a cystic ovary, it would be much safer not to tap, as Tait had so well observed, abdominal tumors upon which it was proposed to operate. Probably it was only in the cases in which there was a single cyst in which any benefit would be obtained. With reference to retroversion being associated with salpingitis, he thought that, in women who had never borne children, lateral version of the uterus was the most frequent displacement; but that in the majority of cases occurring in women who had borne children, especially where there was salpingitis due to septic endometritis, retroversion was almost invariably present. His experience, therefore, was that, in cases in which salpingitis arose from septic-poisoning, retroversion was a frequent accompaniment.

REPORT OF THE COMMITTEE ON MEDICAL EDUCATION.

Dr. C. C. Lee, the Chairman of the Committee on Medical Education, to which was referred, at the last stated meeting, a resolution offered by Dr. Jacobus concerning a State Board of Medical Examiners, reported that, after a full and careful consideration of the resolution, the Committee deemed it inexpedient for the Academy to take any action at present with regard to the subject. The report was accepted.

Dr. F. V. White, Statistical Secretary, reported the death of Jonathan S. Lawrence, M.D.

Dr. F. R. Sturgis made some remarks concerning the establishing of

A STATE BOARD OF EXAMINERS,

through which the licensing power to practise medicine would be divorced from the teaching power, and offered a resolution asking the Academy to endorse the desirability of the enactment of a law to accomplish this end, and also asking that the Academy instruct its delegates to support, at the next meeting of the Medical Society of the State, acts which might be introduced for the purpose of accomplishing this object.

Dr. Roosa seconded the resolution, and remarks were also made by Dr. H. T. Hanks, who thought it best to postpone the consideration of so important a subject until a larger number of the Fellows of the Academy were present.

The President also intimated that this question would be considered somewhat extensively in his valedictory address; he thought that it would be well for the Academy not to commit itself hastily on so important a subject, and suggested that, if the discussion should be postponed until some future meeting, it might be in the interest of all concerned.

Dr. Sturgis accepted the suggestion of the President, and, on motion, the resolutions were laid upon the table.

The Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 24, 1884.

John A. Wyeth, M.D., President, *pro tem.*, in the Chair.

Dr. Frank Ferguson presented on behalf of a candidate a specimen of *tuberculosis of the larynx.*

CATARRHAL PNEUMONIA WITH DIPHTHERIA.

Dr. Van Santvoord presented specimens with the following history: The patient was a child, aged thirteen months, an inmate of Randall's Island Infant Asylum. It had been ailing for about one month, with diarrhœa occasionally succeeding a somewhat constipated condition, and the occurrence of bronchitis some time ago. Prior to the fatal illness there had been no examination of the lungs for several days. On Tuesday night the house physician was called to see the child, when the nurse told him that it had been ailing more than usual for a number of hours. He found that breathing was labored, and on examining the throat discovered a patch of false membrane upon the right tonsil. The child rapidly sank, and died within a few hours. Death occurred within twenty-four hours from the inception of the throat trouble.

At the autopsy the brain presented no very obvious lesion. A patch of pseudo-membrane was found upon the right tonsil, and the epiglottis and the trachea, to about its middle, were coated with false membrane, which, as usual, was somewhat adherent over the laryngeal surface and tonsil, but loosely attached in the trachea. The trachea and large bronchi were injected and coated with copious secretion of muco-pus. About one-third of the lower lobes of both lungs, and about one-half of the upper lobes were hepatized from catarrhal pneumonia. The heart presented no marked lesion, simply a post-mortem clot in both ventricles. The abdominal viscera were normal, with the exception that the solitary follicles were somewhat enlarged throughout the small and large intestines. From about eighteen inches above the ileo cæcal valve to within two feet of the stomach there were six intussusceptions, but these were so frequently found at autopsies in children that they were regarded as having no special pathological significance.

PERICARDITIS AND PNEUMONIA.

Dr. Van Santvoord also presented the heart and pericardium removed from the body of a man who was admitted to the surgical ward of Randall's Island Hospital to be treated for varicose ulcer of the leg. About two weeks before his death he complained of pain in the region of the heart, and shortness of breath with a certain amount of cyanosis quickly developed. On physical examination nothing was found except a rapid action of the heart, with the apex beat on the line of the nipple. No abnormal sounds were heard on auscultation, except subcrepitant râles over the lower lobes of both lungs posteriorly. Within forty-eight hours from the beginning of the attack, bronchial breathing over the lower lobe was heard distinctly. One of the visiting physicians, a competent observer, auscultated the chest and found nothing abnormal with reference to the heart except that there was an increased area of cardiac dulness. The patient died after an illness of two weeks.

At the autopsy the arachnoid showed chronic opacity. The Pacchionian bodies were more developed than usual. There was a certain amount of œdema of the membranes, and some excess of fluid in the ventricles.

Something more than a pint of fluid was found in the left pleural cavity, the lower lobe of the left lung was compressed, and the upper lobe was in a condition of gray hepatization beginning to resolve, and the entire lobe was œdematous. The upper lobe of the right lung was in a condition of red hepatization, passing into gray, the middle lobe was in a stage of red hepatization, and the lower lobe was œdematous, with the upper portion apparently beginning to hepatize.

About eight ounces of blood-stained fluid were found in the pericardium, and the entire inner surface of the sac was coated with a thick layer of lymph. The heart was covered with a large quantity of fat, and all its cavities were dilated. The left auriculo-ventricular opening admitted three fingers, and the right admitted four. The muscular tissue of the heart was moderately fatty.

The liver was normal, the spleen was somewhat shrunken, and the kidneys showed a moderate amount of interstitial nephritis.

The specimen was interesting as showing how easily a prominent lesion might be overlooked by a competent observer.

PLEURISY, PERICARDITIS, AND BRONCHO-PNEUMONIA.

Dr. Van Santvoord also presented specimens taken from the body of a child, about one year of age, that died without a diagnosis. Fluid with exudation of lymph were found in the right pleural cavity. The upper lobe of the lung on the same side, and to a certain extent the lower lobe, exhibited spots of broncho-pneumonia, and a wedge-shaped infarction was seen in the upper lobe near the apex. There was pericarditis over the right auricle, adjacent to the inflamed pleura. The bases of the aortic valves were somewhat roughened.

PROLAPSE OF THE RECTUM.

Dr. Van Santvoord further presented a specimen removed from the body of a child, nineteen months of age, who had suffered from time to time with diarrhœa. The cause of death was bronchitis and broncho-pneumonia. The specimen was interesting as illustrating how the peritoneum might be dragged down with the gut.

BRONCHO-PNEUMONIA AS A COMPLICATION OF DIPHTHERITIC CROUP.

Dr. Van Santvoord said that at the last meeting of the New York Academy of Medicine a difference of opinion arose between the reader of the paper, Dr. Joseph E. Winters, and Dr. John H. Ripley, as to the frequency of the occurrence of broncho-pneumonia as a complication of diphtheritic croup. The position taken by Dr. Winters was that the direct effect of laryngeal obstruction was congestion of the lungs, and subsequent broncho-pneumonia. Dr. Ripley claimed that when the entrance of air to the lungs was partially prevented, instead of congestion occurring as a result, pulmonary emphysema followed, and consequent anæmia of the lung. Dr. Van Santvoord believed that Dr. Ripley's view was certainly that accepted by pathologists in general. Dr. Ripley had also stated that the number of cases in which broncho-pneumonia had been found in patients who had died after tracheotomy for diphtheritic croup was very small, and that, as a matter of fact, the chest was hyper-resonant in cases where the larynx was obstructed, etc., and, consequently, the idea that the performance of tracheotomy was indicated as a means of preventing the occurrence of broncho-pneumonia when laryngeal stenosis exists, was erroneous. The first specimen presented by Dr. Van Santvoord had a bearing upon this particular question. The bronchitis had been recognized prior to the occurrence of the diphtheria, and the diphtheria lasted for only twenty-four hours, while the extent of the broncho-pneumonia was too great to allow of the assumption that it had existed only while the diphtheria existed; in other words, the broncho-pneumonia was the antecedent disease.

Dr. Ripley remarked that, since the discussion at the New York Academy of Medicine, he had seen a number of cases of bronchial croup secondary to tracheotomy. In one he had made the post-mortem examination himself, and in all of these cases the lungs were in a state of distention, and there was no evidence whatever of the existence of pneumonia.

Dr. Van Santvoord further remarked that in his case the lungs did not collapse, as they usually do when the anterior wall of the chest is removed, and that they were anæmic.

Dr. Ripley further remarked that on magnifying the lung where pneumonia does not exist, it would be found that it was in a state of acute emphysema. Furthermore, that there might not be any membrane below the trachea, and but little within the trachea.

TRACHEOTOMY FOR DIPHTHERITIC CROUP.

Dr. H. D. Chapin presented the larynx, trachea, lungs, and heart of a child, three and a half years old, on whom he had performed tracheotomy. He was called to see the child last Wednesday, and found it in a very poor general condition. One week previously it had had general bronchitis, almost reaching the air-vesicles. He prescribed and the patient got a little better. About a week or ten days subsequently he was called and found the child quite ill, with a temperature of 100° F., and on examination discovered a thick membrane covering the soft palate and the back part of the fauces, apparently extending upward into the nose, and there was also pseudo-membrane over the tonsils. It had a slightly hoarse cough, with mucous râles over both lungs.

On the following day the hoarseness of the cough had somewhat increased. Under the use of a solvent spray the membrane began to disappear from the throat. On the following day there was slight dyspnœa. On Friday morning the dyspnœa became intense, all the signs of suffocation developed, and he performed tracheotomy at five o'clock in the afternoon. The temperature before the operation was 99.5° F., and the pulse 140. Within three-quarters of an hour after the operation the temperature was 101.25° F., and the pulse 155. He operated below the isthmus; a large membranous cast of the trachea was expelled, and breathing was relieved at once. During the night after the operation the child breathed easily, but on Saturday morning slight difficulty of respiration was again seen; the respirations, however, were only twenty-four, and there was a slight depression of the upper part of the chest, showing stenosis. The tube was perfectly clean, and there was no membrane in the canula. The difficulty in breathing increased through the forepart of the day on Saturday, and on Saturday afternoon it was as great as it was before the operation, with the respirations about thirty. At five o'clock in the afternoon the child was apparently dying of suffocation. Dr. Chapin then determined to experiment with tripsin. He made a warm solution of the solvent and sprayed it down the tube after removing the inner canula. There was some coughing, and a small portion of the membrane was expelled; the patient then breathed easier. He continued the spraying, and at the end of a few hours the patient was breathing perfectly easy, with the respirations at twenty-eight. During Saturday night the patient breathed easily, and no membrane was expelled. He kept up the spraying steadily, but the child died on Sunday morning of blood-poisoning, with the pulse at 170.

At the autopsy he found the tracheal opening covered with a very thick membrane, but the pseudo-membrane was seen only in patches and soft masses along the trachea and in the bronchial tubes as far as the second bifurcation, showing that the pancreatic extract had digested it. All the lobes of the lungs could be fully inflated with the exception of the base of the right lower lobe, where there were two spots of consolidation.

Dr. Chapin remarked that the tripsin seemed to be a valuable compound in the treatment of these cases,

namely, those where croup existed below the tube. Usually we are powerless to affect the membrane which forms so low down, and if it can be digested by means of tripsin, we may be able to save life in spite of the new formation of membrane.

Another point of interest was the fact that the child, after the first spraying, was anxious to have it repeated on account of the relief which it afforded.

Dr. J. Lewis Smith said: "Tracheotomy seems to have been successful in this case in relieving the dyspnœa, and death occurred from the blood-poisoning instead of the laryngeal stenosis. In discussions in the societies it has been said that severe complications, as pneumonia, or nephritis, or profound blood-poisoning, contra-indicated tracheotomy; that when death would in all probability occur after the operation from such complication it should not be performed, because fatal cases tended to produce hostility on the part of the public to this operation. The correct view, it seems to me, to take of this matter, is that tracheotomy should be recommended, if in however small a degree it improved the chances of the patient's recovery. Our regard and solicitation should be for the welfare of the patient, and not the opinions of the public. I am glad to hear of the encouraging result of tripsin inhalation. I have never seen pseudo-membranes disappear more rapidly from the fauces than when the following prescription was applied by a large camel's-hair pencil every half-hour to the fauces:

"℞. Extracti pancreatis ..... 3 j.
Sodii bicarbonat ..... 3 ij.

"M.—Add one teaspoonful heaped, to six teaspoonfuls of tepid water, and apply by the brush.

"The good result may be partly from the alkali, but I suspect it was largely from the tripsin."

Dr. Wyeth said that in the last case in which he performed tracheotomy he experienced very great difficulty in getting into the trachea. The case he had already reported to the Society, and he would not mention it except for the fact that there was apparently a false impression extant that the operation was an exceedingly easy one to perform. He did not think that he had had an operation during the last six months which had given him more trouble than the tracheotomy in the case to which he referred.

Dr. Chapin referred to a case in which he came near losing the life of his patient on the table on account of a general oozing of blood from the surface of the wound.

Dr. Ripley remarked that he was very glad to hear this expression of opinion concerning the operation from so bold and careful an operator as was Dr. Wyeth, for he did not know of any operation to which he went with more apprehension than to the performance of tracheotomy in croup. With regard to the pancreatin, he hoped that it would prove a success. So far, all solvents which he had employed had been unsatisfactory. In many cases difficulty in breathing can be modified by inhalations of steam.

With regard to the temperature running up after the operation, that had been the general rule in his cases, but it was also a rule that, unless the disease progressed, the temperature fell on the following day. He also thought that apprehension concerning the danger of pouring fluids into the trachea was without foundation, as the fluid could not reach lower than the second or third bifurcation of the bronchial tubes.

Dr. Jacobi said that inasmuch as he had not heard the report of Dr. Chapin's case, there was only one point to which he would direct his attention, if it was necessary, and that was that if there were any disease in which statistical numbers were necessary, it was certainly croup-diphtheria in all its shades, and especially with regard to the fact whether or not diphtheritic membrane would descend into the lower branches of the bronchi more frequently after tracheotomy had been performed than it did in cases in which the operation had not been resorted to. He would only direct attention to the well-known fact that membrane in the trachea, and more often in the bronchi, had a greater tendency to macerate than when it existed elsewhere in the air-passages. In a number of operations where the membrane was already in the trachea, when the incision had been made, loose material would be thrown out, showing that maceration of the newly-formed membrane had already taken place. Thus it was we had so many reports of success following the application of water, lime-water, alkaline washes, extractum pancreatis, etc.; but if there was any place where the membrane macerated easily it was in the trachea and the bronchial tubes, and certainly we wished to have a large number of cases in order to determine whether or not this or that solvent had greater power than those which had been already used.

When croup descended after tracheotomy we found a number of cases in which the children died in a way similar to that in which they did if no operation had been performed, namely, of stenosis, but not to the same extent as when not operated upon.

That meant that the stenosis of the larynx was somewhat different from stenosis of the bronchial tubes. It was true there was dyspnœa, with recession of the supra- and infra-clavicular and diaphragmatic portions of the chest, but it did not obtain to the same degree. There was, besides, when there was laryngeal stenosis, uncomplicated, long-drawn, slow inspiration. It would be found in the vast majority of cases in which there was bronchial stenosis that the respiration was no longer so long-drawn, but was more frequent, and more of the character of the respiration which occurred in inflammatory disease; that is, the breathing when we had the membranous exudation descending was no longer that which arose from pure, uncomplicated croup, but there was a mixture of the inflammatory respiratory disease, and the children did not die alone of laryngeal stenosis, but of the complicating pulmonary congestion, bronchitis, œdema, etc. Dr. Jacobi believed that this fact could be utilized for purposes of diagnosis. In those cases, for instance, in which there was on one day long-drawn inspiration with croupy dyspnœa and on the next day the respirations were quite changed, the recession of the chest-walls was not quite so deep, but the respirations were more frequent and accompanied with cyanosis. Recently he had seen a case of this character. He was obliged to operate, although, he said, it was not an uncomplicated case of laryngeal stenosis, but that the disease had extended downward, and that the lungs were implicated in the process. So it was; for, he found the trachea lined with membrane, and large masses of membrane were thrown out. There was no pneumonia at that time, but there was the descent into the smaller bronchial tubes, which resulted in the relative frequency of respiration.

Dr. Ripley would like to ask Dr. Jacobi if he wished to give out the impression that in laryngeal stenosis the respiration was slow.

Dr. Jacobi answered that he did.

Dr. Ripley thought that this was a mistake. He had the record of over one hundred cases in which the respiration had been invariably hurried. That was not only true of croup, but also of asthma.

Dr. Jacobi believed that he was right in one thing which he had said with regard to Dr. Chapin's case, and it was that, if there was any disease or condition in which a large number, and still a larger number, of observations was necessary, it was certainly with reference to the various manifestations of croup and diphtheria. Dr. Ripley had expressed an opinion exactly the reverse of what he had stated, and Dr. Ripley believed that he was right, and Dr. Jacobi also believed that he was right. Now, Dr. Ripley had had one hundred cases, and he had seen perhaps as many.

Dr. Ripley: "Yes, and many more."

Dr. Jacobi: "I have operated now between four and five hundred times. So it appears to me that his one hundred and my four or five hundred cases do not

begin to be a sufficiently large number to decide that question. I would suggest only this, and I offer it for only what it is worth: Dr. Ripley may observe his cases as accurately as he has already done, and he will find that when there is a decided recession of the supra- and infra-clavicular regions, that where there is laryngeal stenosis pure and simple, the respiration in those cases will be slow—slower than normal. The process is simply a mechanical one, and the observation theoretically is also correct. I shall, however, now proceed to make new observations, and at the end of five years I hope that Dr. Ripley and I will have an opportunity to discuss the same subject again."

Dr. Levi thought that the amount of air required depended upon the capacity of the lung to hold reserved air after each inspiration. When the quantity taken in had been consumed, then breathing began, and in the healthy condition of the lung, with simple laryngeal stenosis, the quantity of air reserved in the lung was greater than that which could be reserved when the lungs became diseased and could not take in the proper quantity of air. The number of respirations, therefore, depended upon the capacity of the lungs to hold the air in reserve after it had been inspired. Theoretically, therefore, he agreed with Dr. Jacobi.

ACUTE PLEURITIS COMPLICATING PERTUSSIS.

Dr. J. Lewis Smith, related the following case: Gertrude I——, aged eleven months, nursing, contracted pertussis about the middle of September, 1884, but progressed favorably with it till the middle of November, when she began to have febrile movement, and respiration was accompanied by an expiratory moan. These symptoms, indicating an acute inflammation, continued, and soon after the resident physician, Dr. Bissell, detected evidences of an effusion in the right side of the chest. Subsequently he introduced an exploring needle at the usual point below the angle of the scapula, but failed to remove liquid. My first examination of the patient was on November 24th, when it was evident from the gravity of the symptoms and the feebleness of the infant that death was not far distant. The pulse was 180, respiration 52, vaginal temperature 103½° F.; marked dulness over the whole right of chest posteriorly and laterally; anteriorly on the same side the resonance was better, though not clear from the clavicle to the nipple, and it was flat below this point; distinct bronchial respiration heard over the entire right side, apparently near the ear; diffuse moist râles also observed in the lung. On the following day the patient was evidently fast sinking, and a more thorough auscultation and percussion was not admissible; respiration 98, temperature 103⅘° F.; pulse very feeble and too rapid to be counted. Death occurred soon after. It will be seen how closely the physical signs and symptoms as ascertained in these brief examinations resembled those of pneumonia.

Autopsy by Dr. W. P. Northrup.—Body well nourished, "a plump, pretty child." Lungs: Right pleural cavity contains sixteen ounces of fluid. This fluid, after standing in a measuring glass a few minutes, separates into a tolerably clear fluid above, at the bottom a sediment of about one-third the whole volume. The fluid is greenish yellow, and the collection of small coagula at the bottom is found under the microscope to be made up of pus cells. The lung is compressed inward and forward, and so devoid of air, in alveoli and bronchi together, as barely to float in water. There are no regions of distinct consolidation, the whole lung having the feeling of muscle. The pleura has a macerated appearance except in one place, about the size of a nickel five-cent-piece, which is thickly coated with adherent fibrin. On section pus exudes from the larger bronchi, and one terminal bronchus is dilated to form a cavity about the size of a pea. The lobes are glued together by recent fibrin, and the lung lightly adherent anteriorly. Liver, spleen, kidneys and stomach normal. Intestines show moderate catarrhal inflammation. The left lung is œdematous—no consolidation and no pleurisy.

Microscopic examination by Dr. W. P. Northrup.—Near the pleura the lobules show a diffuse pneumonitis. In more remote portions the smaller bronchi are compressed; the epithelium has much of it fallen into the bronchi loosely, but there is no infiltration of the bronchial walls. In the lesion of the alveoli are dilated vessels and swollen epithelium.

Remarks.—In children over the age of three years it is not difficult to diagnosticate pleurisy by the physical signs, but in patients under this age, and especially under the age of two years, it is often very difficult to discriminate by auscultation and percussion between pleurisy with effusion and pneumonia. The physical signs accompanying a pleuritic exudation in infants are such, as in the present case, that, if they were observed in an adult, we would unhesitatingly diagnosticate pneumonia. In the infant, enfeebled by disease, the lungs, which are prone in such patients to atelectasis and collapse, are compressed by the liquid before there is any appreciable elevation of the chest-walls or even of the intercostal spaces, and if there be an undue prominence on the affected side in consequence of the effusion, it is compensated by the exaggerated expansion of the opposite lung, which performs the function of both. Measurements, therefore, afford us little aid in the infant. Displacement of the heart is a conclusive sign, but this we lose as an aid in diagnosis if the pleurisy be on the right side. Palpation, in order to determine the presence or absence of local fremitis, and change of position of the patient, in order to determine an increase or recession of the area of dulness if a liquid be present, are for the most part without result in the examination of infants.

In the infant, however great the effusion, it is seldom that we do not hear distinctly the respiratory sound when the ear is placed over the fluid. In the beginning of the attack the murmur may be vesicular, but as the effusion increases it becomes bronchial, and is often as distinctly bronchial and nearly as loud as in pneumonia, as it was in this case. Even in an effusion that is large for an infant, the distance of the lung from the walls of the chest is so small that the respiratory sound is readily transmitted through the liquid, either from the bronchial tubes on the affected side, or perhaps from the other side, so that, as a rule, we hear quite a distinct bronchial respiration when the ear is applied over the pleuritic effusion. This deceives auscultators, and leads them to think that the disease is pneumonia.

The percussion sound is, of course, dull, and nearly or quite flat if there be much effusion. If it be very dull, approaching flatness, over a considerable part of the affected side of the chest, I have been led to regard the disease as pleurisy with effusion rather than pneumonia, whatever the other physical signs in the infant. One would suppose that the exploring needle attached to the hypodermic syringe would always afford a quick and certain means of diagnosis; but, as in the present case, we sometimes fail to obtain liquid by the needle, when it is present, either because there are adhesions or a thick fibrinous exudation at the point of puncture, or because it has not been inserted to the proper depth. Less than half an inch will pierce the chest-wall in most instances, and I think the needle is not infrequently inserted too far.

The chief interest attaching to the clinical history of the present case was the difficulty of diagnosis, and we see why for a long time pleurisy in the infant was supposed to be rare. The mistake is even now frequently made by good auscultators and experienced physicians, as I have at different times observed, of diagnosticating pleurisy in the infant for pneumonia. It seems as if in these times of accurate diagnosis we should be able to discriminate more clearly and accurately the one from the other.

Dr. Van Santvoord thought that the difficulty of differential diagnosis between pleurisy and pneumonia was

not confined to children. He had seen quite a number of cases in which mistakes had been made by competent observers in examining adults. He regarded measurement of the chest and displacement of the heart as two very important physical signs.

Dr. Smith had not noticed any difference in the size of the sides of the chest in cases of pleurisy in children, and when the effusion was on the right side displacement of the heart was not liable to occur.

Dr. Van Santvoord further remarked that he regarded expectoration as an important element in differential diagnosis, although he was aware that in many cases of pneumonia it was absent. In one of the specimens which he presented there was bronchial breathing, transmitted probably through the fluid and through the compressed lung.

Dr. John A. Wyeth presented four specimens containing one point of pathological importance and several of surgical importance. The first was a specimen of

SARCOMA OF THE LOWER JAW,

occurring in a boy eleven years old, A. B——, a native of England. The patient said that about four months ago he noticed "a hunk of flesh" hanging down by a decayed tooth in the lower jaw. This hurt him on eating, and bled at times. He had the tooth extracted, and after that the piece of flesh increased in size. The mother said he had continuous and severe toothache for eight days before this, and also that the glands about the neck did not appear to be enlarged until four weeks ago. On admission to the hospital the alveolar process of the inferior maxilla on the left side, from the incisor tooth back to the last molar tooth, was the seat of a new growth, also involving the cheek and outer side of the inferior maxilla and sublingual gland of the same side; it also extended along the upper side of the inferior maxilla beyond the last molar. The cervical glands of both sides were enlarged. The operation for its removal was performed on November 19th. The point of surgical importance in the case was the fact that Dr. Wyeth kept far away from the periosteum and operated in healthy tissues. The patient made a complete recovery, so complete that it had not been necessary to use a dental apparatus to hold the fragments of the lower jaw in position. Microscopical examination revealed the new growth to be sarcoma.

TWO SPECIMENS OF NECROSIS OF THE LOWER JAW.

Dr. Wyeth also presented a portion of the inferior maxilla removed from a patient seven years of age, who, six weeks ago, had toothache which continued for two weeks. Immediately after this subsided a reddened swelling appeared over the angle of the left side of the lower jaw. There was no history of injury, or of exposure to cold, and the child had always been healthy, except that it had measles when two years old. On admission to the hospital the left side of the cheek, at the lower part, was occupied by a tumor about the size of a hen's egg, which extended from the malar bone down to the angle of the jaw, and backward as far as the lobule of the ear. It was firm and hard, and connected with the inferior maxilla. The integument was freely movable over the tumor, and showed no reddening or ulceration. The teeth were sound. On August 29th a molar tooth was extracted, and some pus escaped. When the probe was passed into the cavity it touched bare bone behind the side of the extracted tooth.

On September 27th the swelling had pointed just behind the angle of the jaw. An incision was made and the probe introduced, which touched bare bone. Operation for necrosis was performed on November 13th. The point of surgical interest was that the bone had an involucrum in which the sequestrum was loose, and Dr. Wyeth thought operations performed early in these cases were not so simple as those in which the operation was delayed until the sequestrum was loose.

Dr. Wyeth also presented the angle, and part of the ramus, of the left lower jaw, which he had removed by operation, and which was accompanied with a history not essentially different from that already narrated.

NEUROTOMY FOR INFERIOR DENTAL NEURALGIA.

Dr. Wyeth reported a case of neuralgia of the inferior dental nerve, in which he performed an operation for its relief—assisted by Drs. Stewart, Ripley, and others—by making an incision down at the upper angle of the jaw, along the border of the inferior maxilla, turning up the flap, dissecting loose the masseter muscle, applying the trephine over a point opposite to the inferior dental foramen, exposing the dental canal, exsecting the nerve to a distance of three-fourths of an inch, and then, with the forceps, stretching the central part of the nerve, and also ligating the inferior dental artery. There had been no pain since the operation.

The Society then went into executive session.

OUR LONDON LETTER.

(From our Special Correspondent.)

LUNACY LAW REFORM—A NEW MEDICAL SOCIETY—REFORM AT THE COLLEGE OF SURGEONS—THE TEACHING OF PATHOLOGY AND OBSTACLES TO ITS STUDY—THE CASE OF EXCISION OF A TUMOR FROM THE BRAIN, AND THE ANTI-VIVISECTIONISTS.

London, January 3, 1885.

The cases of Mrs. Welden and others occurring in the past year have caused considerable attention to be paid to the subject of lunacy reform, both in the profession and outside. It is believed that a member of the government is now preparing a new lunacy bill which will be brought forward in the course of the ensuing session of Parliament. It is generally admitted that many reforms are desirable. The present system of certification of lunatics by any two medical practitioners—in the case of insane paupers by one only—is not satisfactory. It has been suggested that it should be made a rule that one of the certifying practitioners should be either the medical officer of health for the district, or else an asylum medical officer. In the latter case, he should of course be unconnected with the asylum to which the patient is to be sent. A reconstruction of the present Boards—of Commissioners and Visitors respectively—administering the lunacy laws, is also urged. It is stated that the Lord Chancellor recommends the formation of *one* board only to be called the Board of Lunacy.

A new medical society has just been founded under the title of the British Gynecological Society. Dr. Barnes has been elected Honorary President, and Dr. Meadows, President. It is to be hoped that the new society will do a good deal to rescue gynecology from the disrepute it has largely fallen into. It is also to be wished that the question may be settled as to what a gynecologist is, and what he may do. At present, at many general hospitals, those in charge of the obstetric department are forbidden by the rules to perform operations such as ovariotomy, though in some cases they are *permitted*, through the courtesy of their surgical colleagues, to do so. At the meeting which took place last week to institute the new society, Dr. Barnes stated that he had emancipated himself at St. George's Hospital, because it was well known that he could easily find his field outside, if denied him there. He knew full well that the operation of ovariotomy would be refused to his successor.

Reform at the College of Surgeons still lags. The Council have refused to adopt the more important changes urged upon them by the Fellows and members. They have not yet applied for a new charter, without which no important change can be made. Should they do so, the Fellows and members will probably bring all

the influence they can on the Crown to have reform granted *against* the will of the Council, as they can gain so little with the Council.

Pathology is still far from attaining the position to which it ought to aspire. One obstacle in the way of pathological investigators is undoubtedly the limited supply of material. No British pathologist can point to such a roll of post-mortem examinations as those performed by Rokitansky. In London, our pathological material is distributed not only among our eleven teaching hospitals, but also between a host of others, general and special. Each hospital has usually a pathologist, but in those with medical schools attached the lecturer on pathology is not, as a rule, also pathologist, the latter being often regarded as an inferior post, only to be held as a stepping-stone to a place on the staff. A similar separation of the practical and theoretical teaching of pathology obtains elsewhere also. At Edinburgh, Professor Greenfield holds the chair of pathology at the university, whilst Dr. Byron Bramwell is pathologist to the Royal Infirmary, the hospital practice of which is attended by university students.

Where the theoretical teaching of pathology is thus divorced from opportunity for pathological observation and research, it is not surprising that teachers should not only at times sound an uncertain note, but also fail to be in unison. Considering that the lecturers on medicine, surgery, and other branches, all invade the domain of pathology, it is no wonder that, in our present unsettled phase of belief on many subjects, students should be hopelessly confused.

The invincible repugnance of the friends of deceased patients to "allow them to be opened," is often a bar to the pursuit of science. A case recently came under my notice in which the father of a patient refused a post-mortem, and said he had permitted one once on another child who died, and he had never heard the last of it from his wife. His personal objection to it was not unconquerable, but under these circumstances what was he to do? In similar cases I have heard stories of post-mortems being performed unknown to the friends, in cases of great scientific interest. This is a dangerous proceeding and to be deprecated, as there is not only the law to fear, but a prosecution instituted for such a procedure would bring the profession into great odium in the eyes of the public. This has occurred once within the last few years.

The patient from whom Mr. Godlee excised a cerebral tumor has since died from meningitis and cerebritis, although he progressed favorably at first. The anti-vivisectionists have taken the opportunity to air their views in the general press, and denounce the inutility of Professor Ferrier's former experiments on animals to determine cerebral localization. Your readers will not care to be troubled with an enumeration of their illogical statements.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 11, 1885, to January 17, 1885.

HEAD, JOHN F., Colonel and Surgeon. Retired from active service by operation of law, on January 9, 1885, under provisions of act of Congress approved June 30, 1882. S. O. 7, A. G. O., January 9, 1885.

JEFFERSON R. KEAN, to be Assistant Surgeon, with rank of First Lieutenant, December 8, 1884.

BENTLEY, EDWIN, Major and Surgeon. Leave of absence extended two months. S. O. 8, A. G. O., January 10, 1885.

TREMAINE, W. S., Major and Surgeon. Relieved from duty at Fort Porter, New York. S. O. 8, Department of the East, January 12, 1885.

GIRARD, A. C., Captain and Assistant Surgeon. Ordered for duty at Fort Porter, New York. S. O. 8, Department of the East, January 12, 1885.

APPEL, D. M., Captain and Assistant Surgeon. Ordered for duty at Plattsburg Barracks, New York. S. O. 8, Department of the East, January 12, 1885.

GIRARD, J. B., Captain and Assistant Surgeon. Ordered for duty as Post Surgeon at Fort Schuyler, New York Harbor. S. O. 8, Department of the East, January 12, 1885.

HAVARD, VALERY, Captain and Assistant Surgeon. On being relieved at Fort Schuyler, authorized to avail himself of leave of absence (four months). S. O. 8, Department of the East, January 12, 1885.

ELBREY, F. W., Captain and Assistant Surgeon. Sick leave still further extended six months on surgeon's certificate of disability. S. O. 9, A. G. O., January 12, 1885.

PROMOTIONS.

CAMPBELL, JOHN, Lieutenant-Colonel and Surgeon, to be Surgeon with rank of Colonel, December 7, 1884.

ALEXANDER, R. H., Major and Surgeon, to be Surgeon with rank of Lieutenant-Colonel, December 7, 1884.

MCELDEWY, HENRY, Captain and Assistant Surgeon, to be Surgeon with rank of Major, December 7, 1884.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 17, 1885:

THE LATE PROFESSOR WILLIAM DARLING.—At a meeting of the medical class of the University of Vermont held in City Hall, December 26th, the following resolutions were adopted in relation to the death of the late Dr. Darling.

Whereas, it has pleased Almighty God to remove from among us Professor William Darling, and whereas, it seems fitting for us who have been favored with the acquaintance and instruction of one whose intellectual attainments have commanded the highest admiration, whose name will stand among the foremost of his profession, and whose memory will be cherished by all who have had the honor to be his pupils, to in some manner express our deep sorrow; therefore

Resolved, That, while we as a medical class do deeply mourn the great loss we have sustained, we extend to the Faculty of the Medical Department of the University of Vermont our sincere and heartfelt sympathy in the loss of a colleague so able and genial.

Resolved, That we place a fitting emblem of mourning in the lecture-room of the college, there to remain during the remainder of the present session.

Resolved, That a copy of these resolutions be forwarded to the Medical Faculty of the University of Vermont; also one to the Burlington *Free Press and Times*, and the New York MEDICAL RECORD for publication.

B. J. ANDREWS,
B. D. NELLIS.
Committee for the Class.

BURLINGTON, VT., December 29, 1884.

AFFECTIONS OF THE EAR INFLUENCED BY, OR DEPENDENT ON, MALARIA AND DEFECTIVE DRAINAGE.[1]

BY OREN D. POMEROY, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, ETC.

THIS question is beset with difficulties. At the outset we are confronted by the fact that most cases having any symptom of malaria are treated by some salt of Peruvian bark, which exerts, more or less, its peculiar influence on the organ of hearing, making it in some cases simply impossible to determine whether the ear symptoms are dependent on malaria or on the exhibition of quinine. It is sufficiently well known that quinine will congest the cerebral vessels, together with those supplying the scalp, ears, eyes, face, throat, etc., and that this congestion may give rise to swelling and obstruction of the Eustachian tubes, to hyperæmia of the tympanic membranes, and external auditory canals, and even of the labyrinth. In consequence of this the patient will be troubled with deafness, tinnitus aurium, anomalous sensations in the tympanic cavities, with the labyrinthine symptoms dependent on disturbance in its functions, and possibly true disease of the labyrinth itself.

To differentiate, then, between malarial ear symptoms on the one hand, and those dependent on the exhibition of quinine on the other, will present one of the difficulties of the problem before us. Perhaps the earliest and best account of malarial ear affection may be found in the *Monatschrift für Ohrenheilkunde*, No. 11, 1871 (Green's reference and extract), by Weber-Liel. He describes two forms of ear disease, dependent, as he thought, upon malarial poisoning; one an inflammatory affection, which he denominated otitis intermittens; the other a non-inflammatory affection, which he described as otalgia intermittens.

Both varieties of the disease are referred by him to malarial neuralgia of the third branch of the trifacial nerve—the otalgia being a malarial neuralgia, pure and simple; the otitis being an inflammatory affection, the expression of a vaso-motor trophic neurosis accompanying or produced by the neuralgic affection. "After the irritating influence of the malarial poison in the first fever has ended in a severe paroxysm of pain, simultaneously existing in all the branches of the trifacial and neighboring nerves, the malaria is shown for a considerable time longer in the form of a vaso-motor neurosis, as the effect of which there is injection of the tympanic blood-vessels, and a collection of muco-purulent secretion in the tympanum." He describes the symptoms thus: Generally, although not always, there has been a preceding angina or naso-pharyngeal catarrh, when, toward evening or in the night, there is a chill, either decided or perhaps so slight that it is scarcely noticed; this is followed by a feeling of fulness and roaring in the ears, and sometimes by vertigo and pressure in the head. The patient passes a restless night, with profuse perspiration, but on the next day is perfectly well, and the ear symptoms have passed off. Forty-eight hours or so afterward there is another chill, with shooting pains in the ears, deafness, and increased subjective noise, and examination of the ear often shows in this stage an exudation into the tympanum. As the stage of perspiration comes on after the chill, the patient falls asleep, to awaken perfectly well, except that the subjective noises continue.

If the exudation of the tympanum has ruptured through the drum-membrane, the discharge, which was perhaps profuse during the night, ceases by morning, and all pain is relieved. Tenderness of the tragus, which was marked during the pain, is also relieved. Thus the attacks continue, following the quotidian or tertian type, with intervals of perfect freedom from all general symptoms, although the local symptoms in the ears increase in severity, and the intermissions, so far as the ears are concerned, become less and less marked, till finally the ear symptoms are a constant irritation.

Usually but one ear is affected. The mastoid cells may gradually become involved and be filled with pus. Local treatment, even paracentesis of the drum membrane or perforation of the mastoid cells, affords only temporary relief to the constantly recurring attacks of pain. Neither the air-douche, warm or cold water applications, nor morphine injections, prevent the recurrence of the nightly pains. Quinine alone, in large doses, gives relief, and the earlier it is prescribed the more thorough and rapid is its action. The spleen is often found to be enlarged and tender. If the disease has continued for a long time, as it sometimes does for months, till the local changes in the ear have become thoroughly developed, the quinine is then of no value. In all cases of subjective noises and tympanic catarrh dependent upon malaria, large doses of quinine diminish the noises and deafness, while in the more common forms of the disease the same medication has the effect of increasing these symptoms very decidedly.

Professor Voltolini, in the *Monatsch. f. Ohrenheilk.*, May to July, 1878 (Hotz's reference and extract), publishes similar observations, but lays greater stress upon the neuralgic symptoms, calling the affection otalgia intermittens. Hotz again quotes Weber-Liel, in the *Deutsche Zeitschr. f. Prakt. Med.*, 1877, as follows: "Since I first described the otitis intermittens, I have observed a great many cases of acute aural inflammation which belonged to this class, and which, when treated as intermittent otitis, were so speedily cured that I have no hesitation in saying that a great number of acute otitides especially those occurring in spring and autumn, are caused by malarial agencies." James Patterson Cassels, M.D., M.R.C.S., etc., in the *Edinburgh Medical Journal*, vol. xxiii., part 2, p. 910, has an article on "Sewer-gas and Ear Diseases: a Record of Struggles with Foul Drains and other Unsanitary Conditions." His first experience was with his own family. He noticed that his children complained of a general malaise, showed evidence of being out of condition, were dispirited and disinclined to play. All of them showed congestion of the naso-pharynx. On June 29th, a boy, aged eight, had a sudden and painful attack of catarrhal otitis, which was relieved by paracentesis of the membrana.

In a few days there had been eight ounces of serous discharge from the tympanum. He recovered in three weeks by simply keeping the parts clean. On the next day two children, aged eight and ten respectively, were similarly attacked with like results. After a few days a girl, aged three, suddenly became deaf to loud conversation, but with no pain; a quantity of jelly-like mucus was removed from the tympanum by paracentesis. She was

[1] A paper read before the County Medical Society, January 26, 1885.

longer in recovering than the others. He found a cesspool in his yard to be choked, together with sewer-gas in the house from bad plumbing. After this was corrected there was no further trouble. Soon after this a young lady, together with her mother and a governess living in their house, complained at about the same time of a general feeling of being out of condition, with congestion of the naso-pharynx and hardness of hearing. Defective drainage was found, and after being corrected the health of all parties was restored. Another young lady had congestion of the naso-pharynx and catarrhal thickening of the drum-membranes, was languid in mind and body, and the doctor suspected malarial poisoning. She was cured by changing her residence temporarily. Soon after returning to her home she had a low form of fever, and for many months was quite ill. The house was found to be in a very unsanitary condition. She ultimately recovered her hearing by living for a time away from home. Another young lady was affected in a similar manner to the lad of eight years, previously reported. After partial convalescence there was still congestion of the naso-pharynx and persistent deafness. A prolonged residence in London resulted in cure, but on returning to her home she was ill again, went into the country and recovered, when on returning to her home she became ill. She seemed to have caught cold at each relapse. The sanitary condition of the house was found to be very defective. The gentleman of the house was never well while at home, but enjoyed good health elsewhere. Three children had previously died of throat trouble, in this house. An old gentleman with two daughters, all being perfectly healthy, went to live in an old house in the country which was in a bad sanitary condition. The father soon grew very hard of hearing from a naso-pharyngeal catarrh, then the eldest daughter became deaf from the same cause, and subsequently the younger was found to be growing deaf. No treatment seemed to benefit. This house was also very damp. Three other young ladies complained of general malaise and hardness of hearing. They lived in an old house in the country which was in a damp unsanitary condition. They all became convalescent on living for a time in a different neighborhood.

It is worthy of remark that in several of these houses dampness was mentioned, which is so potent a factor in developing catarrhal otitis. The fact that convalescence occurred after the patients were removed from the offending houses does not quite prove that the unsanitary condition perpetuated the disease, for it is well known that change of air will often greatly benefit a patient having catarrhal otitis, whether the new conditions are more healthful or not.

The famous case of Dr. S——, under the care of Dr. Roosa, reported fully in the last edition of Roosa's "Treatise on the Ear," may fairly be regarded as an ear affection caused, or at least modified, by defective house-drainage. The doctor was at the time forty years of age, had been working hard for a long time in his editorial labors, was known to have been anæmic for more than a year before the attack, and had been afflicted with neuralgia about the head and face. Dr. Roosa sums up the case by saying, "It was simply a case of subacute non-suppurative inflammation of the Eustachian tube and tympanic cavity, occurring in an anæmic and consequently neuralgic . . . subject." The affection continued from May 5, 1879, with varying results, until June 19th. A great variety of opinions were expressed by different consultants. The drum-membrane was incised, as well as the meatus and the tissue over the mastoid process. All of the more usual remedies were employed with uncertain effects, until, on May 28th, as the result of a consultation, quinine in large doses was suggested—with the idea that the pain might be neuralgic, and this dependent on malaria (or sewer-gas?)—to be followed up by arsenic. This modified the pain so that smaller injections of morphine sufficed. On June 12th, as the result of another consultation, whiskey was ordered to the amount of two ounces every three hours with milk and other nourishment, besides citrate of quinine and iron. The patient during the next week became nearly convalescent, with the addition of other means of relief suggested by the indications. It was believed by Dr. Roosa that the essential condition of the patient, independent of unpleasant complications arising from operative interference, depended on the bad influence of defective plumbing, together with the depression resulting from constant overwork.

Dr. J. Orne Green's case, from the *Amer. Jour. Otol.*, April, 1879, is as follows: M——, aged twenty-three, applied to the Boston City Hospital, in October, 1878, for pain in and discharge from the left ear. Meatus narrow from a hyperostosis; abundant muco-purulent discharge; membrana nearly destroyed; granular condition of the tympanal lining, and obstruction of the Eustachian tube. Local treatment was applied for two weeks, when she was much better. One week after this she had pain in her right ear from a catarrhal inflammation of the tympanum. Politzer's inflation greatly improved her. During the next three weeks she was seen several times, and she had pain and discharge sometimes from one, and then from the other ear. Right membrana then had a small perforation.

In December the doctor found that he was dealing with an intermittent catarrhal inflammation of the two tympana. First one ear discharged for one or two days, would cease, and the other become similarly affected; the disease returning to the former ear, with repetition of the symptoms. At this time, on almost every evening, at about 6 P.M., she had pain in the face, teeth, head, and around the ear, soon became chilly, with flushed face, continuing until 10 P.M., when she retired, began to perspire, and by 11 P.M. the pain would be relieved, and she would sleep till morning. These pains were sometimes on one side and then on the other, and were followed by inflammation, with discharge from the ear of that side. She was employed in a boarding-house in Boston, situated on what is called "new land," but with no suspicion of malaria in the neighborhood. Defective drainage, however, was suspected. During the summer a child was ill with diphtheria, and was removed by the order of a physician. In October a lady died of typhoid fever. There was an ill smell about the house. In December a daily record of the patient's condition was made from the 13th day until the 28th.

December 13th.—Chill about 6 P.M.; pain in right cheek and ear, followed by fever and perspiration.

December 14th.—A little fever in the evening.

December 15th.—Chill at 6 P.M.; pain and throbbing in left ear; pain around both ears, and, in mastoid regions, fever and perspiration.

December 16th.—Muco-purulent discharge from the left ear; tinnitus and vertigo. In the evening slight fever; little pain in both ears.

December 17th.—Membrana of left very red and secreting; right free from congestion; small perforation; perforation whistle dry; slight fever; little pain in both ears.

December 18th, 19th, and 20th.—Both ears free from congestion; no symptoms.

December 21st.—Chills, with pain and throbbing in the left ear; swelling of left side of the face; fever and perspiration.

December 22d.—Discharge from left ear in the evening; same history as on 21st.

December 23d.—Same as 22d.

December 24th.—Discharge from left ear ceased; little fever.

December 25th.—Chill, fever, and pain in right ear and face.

December 26th.—Right membrana very red.

December 28th.—A thin muco-purulent secretion discharging through a small perforation in right membrana; tumors about the ear sensitive to touch.

She was then sent to the hospital, when she complained of nausea in the morning, pains in the limbs and left side, besides other symptoms, which caused the diagnosis of hysteria to be made.

After leaving the hospital the doctor saw her at irregular intervals. She had chills occasionally, but at longer intervals; fever and sweating less frequent; more or less constant headaches, neuralgic pains in the face, nearly constant nausea for a few days at a time, with occasional vomiting; inflammation in left tympanum constant, the discharge ceasing in two weeks, but with no attempt at a reparative process.

Right tympanum became congested and discharged for a few hours about ten days after leaving the hospital; the perforation after a time closed. The chills never went beyond a decidedly cold feeling. Flushing of the face was very marked; perspiration profuse. The hyperæsthesia during the pain was extreme. The loss of membrane in one side, the doctor concluded, occurred before this attack, and that this differs from an ordinary form of catarrhal inflammation in the preceding slight chill, in the marked neuralgia of the trifacial, in the fever, swelling of the face and hyperæsthesia, in the relief of the neuralgia by the perspiration, and "in the congestion and discharge from the ear following the other symptoms after a few hours usually, and coming on rapidly and diminishing with nearly equal suddenness; these attacks recurring every few days for four months." The direct connection of the aural affection with the neuralgia—or with the cause of the neuralgia—was so decided that it could not be denied. He concludes that his case is quite similar to those described by Weber-Liel in the *Monatschrift für Ohrenheilkunde*, No. 11, 1871. The cause of the disease seemed obscure. The patient had always lived in Boston and its vicinity, and had not, as far as the doctor could judge, been exposed to malaria. He was inclined to ascribe sewer-gas as the cause of the trouble, and calls the affection "otitis intermittens."

In the *American Specialist* for March 1, 1881, F. C. Hotz treats of this subject and refers to a typical case of otitis intermittens, in which, after all other means of relief had failed, the intermittent character of the disease was demonstrated by the speedy relief obtained from the use of quinine. Another class of cases, which were promptly relieved by quinine, showed a remarkable intolerance of applications to the ear, and a great disproportion between the objective changes observed in the auditory canal and middle ear and the degree and extent of the subjective symptoms, the patient showing great nervous prostration with so violent pain in the ear and head as to remind one of the severer forms of suppurative inflammation, while the objective symptoms were those of a comparatively mild form of catarrhal otitis. He reports a case where the most gentle injection of warm water was so painful as to produce a fainting fit. This case had followed a malarial attack; it was that of a married lady, thirty-six years of age, suffering from violent earache. She had an attack of malarial fever three weeks before the attack of otitis. She also had had an attack of intermittent fever several years previously. The last attack was speedily arrested by quinine, which was discontinued with the subsidence of the fever. One week after the termination of the fever the patient was seized with a neuralgia in the left side of the head, extending to the left parietal bone, which during the attack was tender to the touch. These attacks recurred daily, subsiding in the latter part of the day; the post- and infra-auricular regions became swollen, and after one week a slight discharge appeared from the ear, when the neuralgia only appeared every second day and with a shorter duration. The auricle, meatus, and adjacent parts were normal. The membrana was very red and swollen; a small perforation was seen in its ant. inf. portion. Syringing caused great pain and the patient fainted. Quin., Dover's powder, and warm water dressing were used. Two days after this the discharge had ceased, the perforation had nearly healed, and there was no pain. Hearing decidedly improved; continued only the quinine. Two days after this the pain had returned, the membranæ were swollen, and a slight discharge was noticed; quinine was given in two-grain doses every two or three hours.

Six days after this—she had been free from pain since the last note—no more discharge, no longer sensitive to touch; perforation healed, membrana opaque; watch heard at ten inches, which at first was not heard at all. In the *Archiv. Otol.*, vol. ix., p. 245, the same author reports a case of otitis intermittens as follows: A man, aged forty-eight, had a violent middle-ear inflammation of the left ear, which had continued for three weeks before the doctor saw him (March 2d). The most severe pain was in the left parietal bone; muco-purulent secretion in the meatus, the latter being red and much swollen; membrana red, swollen, infiltrated, and perforated. H. D. L. watch 0., tuning-fork heard by bone conduction better than in the other ear. H. D. R. watch $\frac{1}{24}$". Patient had tertiary syphilis. Treatment: boric acid wash and ten grains of pot. iod., ter in die, continued for four weeks. This resulted in no change of symptoms.

March 29th.—No improvement, except meatus less swollen; pain moderate, but violent yesterday; touched edges of perforation with cup. sulph.

April 1st.—Violent reaction from the cup. sulph., but the ear now is about the same as on the 29th. Touched granular edge of perforation with a ten-grain solution of arg. nit.

April 5th.—About the same reaction from the arg. nit. as from the cup. sulph. In neither instance were the topical applications severe, and a morbid irritability of the part was suspected. After more than four weeks of treatment there was no improvement. At this juncture it was discovered that the patient had had a good day and then a bad day, and that on the latter there would be pain in the ear and discharge, with soreness around it, the pain increasing until the afternoon, when a profuse perspiration brought relief. He lived in a very malarious locality. Ordered two grains of quinine every hour.

April 8th.—Took twenty grains of quinine every day; had one moderately "bad" day. To-day should be a bad day, but he escaped.

April 12th.—No pain since the 6th; all the symptoms have nearly disappeared; very little discharge; the large doses of quinine disagreeing, he was ordered eight grains a day.

April 20th.—Drum-membrane 'healing'; hears a watch in contact, and the voice well.

May 20th.—Been taking quinine irregularly, but is well.

Dr. Hotz refers to a case of Dr. Roosa's, published in the *Arch. Otol.*, which local treatment aggravated, but which was rapidly improved by quinine. Dr. Hotz regards this intolerance of local treatment and the prominence of nervous symptoms as an evidence of the malarial character of the disease. He, with Voltolini, agrees that small and frequent doses of quinine are preferable in these cases to the larger and less frequent.

In the *Archiv. Otol.*, vol. iii., p. 97, Dr. C. J. Blake reports on 1,652 cases of ear disease, among which are two cases of otitis intermittens. These were males, subject to malarial fever. Their symptoms were neuralgic pains in the ears, congestion of the membrana and secretion in the middle ear, which occurred at the period of symptoms of malarial poisoning, and subsided with the disappearance of these symptoms. Local treatment did no good, but quinine promptly gave relief. Dr. Rossi, of Rome, *Archiv. Otol.*, vol. ix., No. 2, "Progress of Otology," in a report on 364 ear patients, observed one case of neuralgia of the tympanum, dependent on malarial influence, which was promptly relieved by quinine.

In "Ziemssen's Cyclopædia," p. 621, under the head of "Chronic Malarial Infection," appears this statement: "Patients thus affected complain of dizziness, ringing in the ears," etc., and on p. 614, under the heading of

"Remittent and Continued Malarial Fever," appear these among other symptoms: "Severe headache, dizziness, ringing in the ears," etc. In the Cincinnati *Lancet and Clinic*, October 6, 1883, Dr. Seely makes the statement that he has seen one or two marked examples of serous effusion into the tympanum due to malarial influence.

The following case was treated at the Manhattan Eye and Ear Hospital, September 26, 1883. It was that of a man, aged twenty-nine, who in July last caught cold in the left ear; suffered pain for two weeks, when rupture of the membrane and discharge relieved the pain, the discharge soon ceasing. About three weeks previous to admission to the hospital the pain returned in the same ear, soon followed by discharge. Pain was not now relieved by the discharge, and extended well over the side of the head, including the occiput; hearing was nearly abolished. Some granulations were removed from the tympanum, leeches were employed to relieve the pain, but with only partial success, as the hemicrania returned, and on October 1st it was relieved by ten grs. of quinine, t. i. d. Since this time there has appeared a spot of tenderness behind the angle of the jaw, and the pains in the ear and head have returned in spite of the quinine. Other means of relief failing, and there being considerable discharge, on October 8th a 40 gr. sol. of arg. nit. was poured into the meatus and allowed to remain. On October 10th pain and discharge ceased. Same application repeated on the 12th. H. D. watch 1"; perforation healed. October 15th, hearing still improving, and he was sent home; no further symptoms.

This patient came from a very malarious region up the river, had recently had malarious symptoms, and I infer that the prompt action of the quinine in relieving the pain was an indication of its malarious nature, though *proof* of this does not absolutely exist.

With a view of determining the opinion of aurists on this subject, I have addressed notes to about thirty-six prominent aural surgeons in this country and Canada, twenty-eight of whom have replied. Among those whose replies bear on the subject I may refer to the following:

Professor E. L. Holmes, of Chicago, writes: "I am sorry to say I can contribute so little to aid you in your effort to determine the facts bearing on malarial diseases of the ear. I have seen many cases of disease of the ear, modified by malaria, and have prescribed quinine in nearly every case of continued inflammation of middle ear, especially if accompanied by *much* pain; in fact, this is so much a habit, that I have little experience in knowing the course of inflammatory diseases of the ear without quinine."

Dr. H. G. Miller, of Providence, writes: "I do not think of any cases of ear disease which I can describe with certainty as malarial. I have seen not a few in which I had reason to think malaria entered as an element. But as there has generally been previous catarrhal trouble, and as, in almost every case, quinine had previously been freely given, I have found it very difficult to make a satisfactory distinction. I have simply said 'chronic or acute catarrhal otitis media complicated with malaria,' or, 'aggravated by quinine.'"

Dr. Clarence J. Blake, of Boston, writes: "I have no experience in malarial affections of the ear to any extent except in cases which I have had from the West—chronic cases in which large quantities of quinine have been taken. We have as yet no malaria in Boston, though I suppose we may expect it in time."

Dr. St. John, of Hartford, writes: "I cannot say that I have met with many ear affections which I regarded as distinctly malarial. Of course I see many who date their trouble from a malarial attack, but usually speak of having taken a great deal of quinine, which somewhat complicates the etiology. I have had no cases of *acute* aural disease which I thought were due to malaria."

Dr. W. H. Carmalt, of New Haven, among other things, says: "I have met a few cases where the patients reported that their attending physician had ascribed their deafness and tinnitus to malaria, but I have always found sufficient chronic middle ear or posterior nasal trouble (catarrh) to account for it all."

Dr. Albert H. Buck, of New York, replies, in substance, that possibly acute and chronic affections of the ear may be caused by malaria, but "I possess no proof nor any facts tending to favor such a belief. In three or four of my mastoid cases I have observed (on the second or third day after the operation) a rise of temperature and a general depreciation of the patient's physical tone—loss of appetite, increased discharge of pus from wound, return of headache, rapid and feeble pulse—which I ascribed to malarial influence, and which condition was gradually relieved by large doses of quinine (fifteen to thirty grains daily for a few days). I have seen only a few cases of otalgia which I suspected to be of malarial origin. I say 'suspected' for I never could reach anything more definite than a mere suspicion. The success of quinine in relieving ear symptoms favors a malarial theory of origin, but certainly does not prove it." [This in response to specific questions from myself.]

Dr. W. W. Seely, of Cincinnati, writes: "I fear I am not yet able to formulate my experience with 'malarial affections of the ear.' I certainly have seen an example—probably examples—of effusion (serous) into the cavitas tympani due to malaria, one case occurring in a man[1] who was suffering from malarial albuminuria, which I diagnosticated by getting the special and general two and two together, and the patient promptly recovering under the quinine internally, and the ear under inflation simply (no paracentesis, an operation I never make for serous effusion). I presume every one has seen samples of otalgia due to malaria, and promptly relieved, of course, by quinine. Twelve or fifteen years ago I had my attention called to a child in the ward by the nurse saying that every afternoon it began to fret and cry, and soon a discharge would occur in one ear. I found her report true, and gave the baby quinine, without any direct treatment of the ear, prompt relief following. About a year before your famous New York case (Dr. S—— (?)), a man came over from Indiana to consult me for a bad otorrhœa, facial paralysis on the same side, and intense pain in mastoid, and great tenderness on pressure. While everything seemed to point to mastoid disease, he gave a history that had an appearance that led me to keep him quiet, giving him potass. bromid. for the first night and, while it had done no good and things looked the same, I, notwithstanding there was no 'periodicity,' concluded I would take another night, and give him twenty grains of quinine. The next day he had no pain or tenderness, and had slept perfectly. While the facial paralysis persists, the ear is well, or was the last time I saw him. Under ordinary circumstances, and acting under the incision or trephining 'habit,' one would have hardly avoided opening the mastoid. I am constantly in the habit of giving quinine under all circumstances, even in acute otitis media catarrhalis, or purulenta in children, where there seems to be indications, and expect, and find so far, only benefit; in this regard my experience not coinciding with that of Buck (?). I don't know that I *have* illuminated much the points you may have in mind. Possibly catechising may bring out more, and I'll gladly submit to it."

Dr. Samuel Theobald, of Baltimore, states that he has not found malaria to be associated with ear affections, but notes the fact that an obstinate form of keratitis often follows an attack of malarial fever. He propounds my query to Dr. S. L. Frank, of Baltimore, who recalls a single case of distinctly intermittent tinnitus, dependent on malaria, which was cured by the administration of arsenic and quinine.

Dr. H. N. Spencer, of St. Louis, writes: "In malarial infection and concomitant aural disease, I have not been able to trace a connection, as cause and effect, in a single

[1] In the case reported here, of course, others would claim, and perhaps with truth, that the tympanic effusion was simply due to the albuminuria.

instance. Where they co-exist, the inducing cause will be found to have co-existed. For my part, all that I can say is: 1. The constitutional effects of a malarial poison will have a prejudicial effect upon an ear disorder, whether pre-existent or concurrent, *without changing its nature at all.* 2. The therapeusis of malaria, as ordinarily practised, *may* exercise an unfavorable influence upon the ear in health or disease. In the malarial regions of this *climate* aural diseases are very prevalent. In more intense malarial regions than this, having an equable climate, as the Southern coast, ear troubles do not prevail to a marked extent. The intermittent character of symptoms in some aural affections, I feel inclined to ascribe to 'nerve fatigue' rather than to a malarial origin. Indeed I have more frequently found this phenomenon disassociated from a malarial history."

Dr. C. H. Burnett, of Philadelphia, writes: "I have never observed what I could call a malarial ear disease. I think, furthermore, the term as used by some writers needs a clearer definition."

Dr. Charles A. Todd, of St. Louis, among other things, says: "It is customary here to give quinine freely in 'catarrhs' with persistent fever, in which cases the ears are apt to be involved, secondarily probably. We have also to deal with tinnitus, ascribed by the patient to the 'effects of quinine' given to break up ague."

Dr. J. Alfred Andrews, of New York, writes: "Last autumn I looked up my ear cases for the purpose of ascertaining to what extent intermittent fever was responsible for middle-ear trouble. I find that on Staten Island many of the ear patients had had chills and fever at some time antedating their ear trouble, but the majority of my cases had never had the 'ague.' Since the Staten Island Eye and Ear Hospital was inaugurated last May, I have had better opportunities for inquiring into the question, but I am not yet sufficiently advanced in my opinion to offer any positive data in regard to the malarial nature of some cases of ear disease. I have seen an acute exacerbation of middle-ear trouble which I believe to be distinctly traceable to the malarious attack. In my own house I have seen a case of otitis media cat. subacut., which I was convinced was due to malarial influence; but this is an isolated case, and similar opportunities are rarely offered. I have myself had intermittent fever, and frequently had occasion to test my hearing during the attacks, which, four years ago, were of almost monthly occurrence, but I never noticed any deviation from the normal condition."

Dr. S. O. Richey, of Washington, writes: "In my opinion it (malarial influence) sometimes intensifies the impairment of hearing, with a given pathological condition in chronic otitis of the non-suppurative form. I feel sure that it increases the tinnitus in cases where it already exists, but whether it ever induces it (the tinnitis) or not I cannot decide. It probably does, by the disturbance of the general circulation incident to it (the malarial condition?). Quinia so frequently produces tinnitus in such cases that its effects often, I think, disguise the effects of the ague itself. The tinnitus is that which you have often noticed in anæmia. Malaria in its acute form has seemed in one or two instances to retard recovery in the chronic form of suppurative inflammation. Other than this I have noticed nothing which I could attribute to it, except as it influences any affection from which the individual may be suffering at the time."

Dr. R. A. Reeve, of Toronto, writes: "My experience of strictly malarial affections of the ear has been so limited, I can at present recall but one definite example, and of that I cannot furnish notes."

Professor S. J. Jones, of Chicago, writes: "I have never yet been able to diagnose 'malarial affections of the ear.' By this I mean primary affections of the ear, due solely to malarial poisoning. That malarial poisoning may complicate existing inflammation of the ear, or may even cause a neuralgic pain in the ear, may readily be conceived, but that malaria produces primary affections other than neuralgia, I need further evidence to convince me. That acute otitis media may subside after the administration of large doses of quinine does not prove that such subsidence was not in spite of its administration, and not necessarily because of it."

In conclusion, I will simply say that, as far as I have been able to study this subject, I am inclined to the belief generally obtaining in the replies from aural surgeons herewith read, that is, that malarial and unhygienic influences from bad house-drainage exert a modifying influence on ear affections, which are not necessarily peculiar in their manifestations, and not in those opinions entertained by Weber-Liel, Voltolini, and Hotz.

ON DEBOVE'S NEW TREATMENT OF GASTRIC ULCER—THE HABITAT AND TREATMENT OF THE OXYURIS OR ASCARIS VERMICULARIS.

By HENRY B. MILLARD, A.M., M.D.,

NEW YORK.

In a communication made to the Société Médicale des Hôpitaux in April, 1884, and in the *Progrès Médical* of July 12th of the same year, Dr. Debove promulgated a new treatment of a malady which may justly be termed the *opprobrium medicorum*, namely, gastric ulcer, illustrating the practical view of his theory by presenting the records of four cases which he had cured. His idea is to spare the stomach the necessity and labor of excessive muscular action, and the stretching and pulling, as it were, of the new tissue necessary to the healing of the ulcer, giving it rest; and as the secretion of the gastric juice cannot be suppressed, to modify its acidity, which, though necessary to gastric digestion, is, nevertheless, to an ulcer, a caustic irritant; using such food as does not require peptonization by the stomach, and can be digested entirely in the small intestines. Under such favorable conditions the ulcer may heal with comparative ease.

Dr. Debove showed me, in the summer of 1884, his method of treatment, and I saw and examined a number of patients cured or relieved by it. The lacteal diet usually employed, consisting in the administration of several quarts of milk daily, is sometimes provocative of hemorrhage from distention of the stomach, and not only that, it is usually inefficacious. Dr. Debove, after having used with advantage nutritive powders, condensed milk, etc., conceived the idea of relieving the stomach entirely of the chemical part of digestion, and neutralizing the acidity of the gastric juice by administering the powder of beef and milk, or water mixed with the bicarbonate of soda. That the gastric juice does not act upon this mixture is shown by the fact that, upon removing a portion of it by the tube from the stomach after a certain time, it is found to contain no peptones. The work of converting albuminous substances into peptones is thus taken off the stomach, and the ingesta is passed unchanged into the duodenum, only in a more highly alkalized state, being thus all the more favorable for intestinal digestion. That peptonization by the stomach is not always necessary to digestion, is evident from the fact that the pancreatic juice liquefies the muscular and other tissues separated, but not dissolved, by the gastric juice, and that this latter, indeed, does little more than separate the elements of the food; and if certain forms of fatty matter and nitrogenous substances in divided particles, and free from fibre, tendon, etc., could be introduced directly into the duodenum, the stomach might to a considerable extent be dispensed with.

As to the "alkaline cachexia" being produced by the administration of an ounce of the bicarbonate of soda daily, he cites Jaccoud, who gave, for a long time, twenty grammes, and Charcot, who had given forty grammes daily, without any ill effect, but admits that although the cachexia may not be established, the remedy may cause

inconvenience; its taste is disagreeable, and it is somewhat irritating to the stomach, and its decomposition by the gastric juices gives rise sometimes to the formation of considerable quantities of carbonic acid gas, causing painful eructations. He advises its use, therefore, when it does not agree, in smaller doses. On account of these objections he tried lime-water, calcined magnesia, saccharate of lime, etc., but abandoned them in favor of the soda. In employing this treatment the stomach is first washed with simple water to free it from acidity, using Debove's modification of Faucher's tube. (A full description of the method of lavage by this tube was given in a paper by me in *The New York Medical Journal* of April 19th and 26th, and May 10, 1884.) This operation should be performed by, or under the direction of, the physician himself, on account of a possibility of hemorrhage being produced. The operation should be suspended if the water is returned tinged with fresh blood, but otherwise continued until what comes from the stomach is quite clear. As to the danger of hemorrhage from *lavage* it has never occurred in his cases, but he instances two (which have been published) where it occurred to a fatal extent, and was supposed to have been produced by the *lavage*. At all events, it is a danger that should not be overlooked. Debove usually gives twenty-five grammes of the *poudre de viande* with ten of the bicarbonate of soda, prepared with milk, so as to be of about the consistence of cream, administering it, when it cannot be taken otherwise, by the tube. That Dr. Debove's ideas are not chimerical is evident from some very remarkable cures which he has effected, three of which I will refer to, as I myself saw and questioned the patients. The most remarkable was that of Louise Davit, whom I saw at the Hôpital des Tournelles, where Dr. Debove is at present physician-in-chief; she was thirty-nine years of age, and had had for twenty years a gastric ulcer, and during this period had suffered frequently from exhausting hemorrhages, and, as a matter of course, from severe gastric pains. So imperfectly had her system been nourished for many years that she looked a dried-up woman of sixty-five. She was, when I saw her (last August), entirely cured, and serving as an assistant in the wards; and was able to digest ordinary food; she had been under treatment for nine months. At first, fifteen to twenty grammes of soda were given daily, the quantity being gradually increased to thirty—about one ounce.

Hôtel Dieu, August, 1884.—The patient was a man forty-five years of age; the gastric ulcer had existed nine or ten months; had been subject for three months to gastric pains and violent hemorrhages. Is now taking ninety grammes of the *poudre de viande* daily, and six grammes of the bicarbonate of soda immediately before the beef powder, in a little water. The hemorrhages have stopped and the pains entirely gone.

Hôpital des Tournelles, August, 1884.—Patient a woman; the gastric ulcer had existed eight months, with severe vomiting and hemorrhages. Has been under treatment six weeks, and is now quite cured. No restrictions now as to diet. The beef powder and soda were given mixed with milk at the commencement of the treatment.

I regret that I cannot supplement these cases by experiences of my own, but I have had no cases of gastric ulcer since becoming acquainted with this mode of treatment.

OXYURIDES, OR ASCARIDES VERMICULARES, THEIR HABITAT AND TREATMENT.

It is but little creditable to many, I may say most, writers on diseases of children, that they usually state that the ascaris oxyuris mostly infests the rectum, and the blind acceptance by me of this common statement, rendered the cure of two cases well-nigh impossible. To find out their habitat and character it is necessary to consult specialists in this department, and not rely upon works on general practice or on the diseases of children. Kuchenmeister[1] states that they inhabit the large intestine, especially the cæcum and rectum; and Cobbold says: "It is an error to suppose that the lower bowel or rectum forms their especial habitat, nevertheless the most approved manuals, *vade mecums*, and general treatises have for a long time supported this general view."[2] And according to the same author, "they commonly infest the terminal portions of the intestinal tube, being especially abundant in the sigmoid flexure of the colon."[3]

Leuckart says: "Their only natural abode is the large intestine, the whole length of which is often inhabited." . . . "They are also found in the cæcum and the small intestine."

With cases of ascarides, occurring so frequently as they do in children and adults, we are all familiar, and there are usually no insuperable difficulties in affording relief by the constitutional and local means of treatment usually employed, the latter being most generally used on the theory that the ascaris inhabits the rectum solely, and that this should be made the point of attack; still, many of these cases are very troublesome. The two cases to which I have referred, however, are as follows: Six years ago, Miss X——, then seventeen years of age, had a rectal abscess resulting in a fistula; this was successfully operated upon by Dr. J. C. Minor; it had been preceded by other abscesses. She had since infancy been troubled at various times by ascarides, and for two or three years they had been more intolerable than ever. Injections of nitrate of silver, strong infusions of the seeds of chenopodium, etc., always produced relief, but this was only momentary; internal remedies were also given, but as it proved, not enough reliance was placed upon them. I believe that the rectal abscesses, so severe and incessant almost was the itching, were caused by the parasites; they were so troublesome as to prevent sleep and were voided, according to the young lady's expression, "almost by the cupful," and she often found them on her clothing. The matter of diet was not overlooked. She was particularly fond of old cheese, and this, with many other things, was prohibited. The fistula was cured, and the ravages of the ascarides kept in check more or less satisfactorily, mostly by an injection at bedtime of semina chenopii. Toward the spring of 1884, however, her sufferings became so great that she was obliged to seclude herself to a great extent from society. For a young lady of twenty-three, refined, and noted for her beauty and accomplishments, this was a humiliating malady, not to take into consideration the extreme suffering entailed; had this continued much longer I think her reason would have become impaired. As my treatment had thus far been ineffectual, I determined to make an exploration of the rectum, which I did with a long two-bladed speculum. I found the mucous membrane swollen and dark red, the hemorrhoidal veins prominent and coated with mucus, and there were superficial erosions. I applied to the whole surface of the rectum a solution of thirty grains to the ounce of nitrate of silver, which produced relief lasting several days, and was followed by exfoliation; several other applications produced the same effect, but the benefit was not lasting. I thought I might have overlooked some pocula or sinus, and requested Dr. Minor to see the case, as I was about in despair; he examined the rectum with me but could not discover nor suggest anything different. The condition of the rectum at this time seemed pretty healthy. Upon making a later examination, however, I noticed, oozing from the sigmoid flexure of the colon, a quantity of jelly-like mucus in which there were a few oxyurides.

This discovery at once determined my course of action, and entirely discarding any more local treatment, I prescribed forty-five drops of Parke, Davis & Co.'s ext. fl. cort. rad. granati before each meal, and a grain and a half to two grains of santonine between meals and at bedtime, giving the latter remedy cautiously, as it sometimes de-

[1] Die Parisiten. Leipsic, 1855. [2] Parasites. London, 1879.
[3] Entozoa. | London. 1874.

velops poisonous effects unexpectedly. As there was more or less constipation, I ordered every morning one of the sulphate of soda waters, sometimes Pullna and sometimes Marienbad. I will terminate my account of this case by saying that these remedies effected a cure in a few weeks, and that the patient has remained well since, a period now of eight months.

The anthelmintics, however, I am convinced, would not of themselves have effected a cure in this case, as they afforded only limited relief, till I prescribed with them the sulphate of soda waters. I believe these were of great service in destroying the mucus in which the worms had their nidus, and I have found them of great value in all forms of intestinal parasites.

The second case was that of a married lady from a neighboring State, who had been under the care of a number of physicians at home, and had undergone a great many varieties of treatment without benefit. The local irritation had engendered insomnia, hysteria, and a condition bordering on nymphomania. I prescribed injections of the infusion of chenopodium at bedtime, and availing myself of the experience I had recently acquired, at once resorted to the same treatment I had employed in the case of my first patient, and with a similar happy result. At first neither the cæcum, rectum, nor colon can be positively designated as the region mainly or entirely infested; when it is the former, attention to the general health, a relaxed condition of the bowels, and local injections of various kinds will often prove sufficient; but when these measures are not followed by rapid improvement, it may be assumed that other portions of the intestinal canal are inhabited, and whatever other treatment seems most indicated, should be resorted to without delay.

It is *since* the cure of these two cases that I have ascertained what Cobbold and Kuchenmeister, as well as Leuckart, say. I should have saved my first patient a good deal of distress had I ascertained earlier, though the local applications corrected a very unhealthy condition of the rectum.

I may add that the opportunity is not very likely to occur to any one of actually *seeing* the oxyurides emerging from the sigmoid flexure into the rectum.

VESICO-UTERINE FISTULA — OPERATION — RECOVERY.

By HAMILTON WILLIAMS, L.K.Q.C.P.I., L.M.,

GREENPOINT, BROOKLYN, E. D.

LATE MEMBER MEDICAL STAFF, COLONIAL OFFICE, DOWNING STREET, LONDON.

THE following case may not prove altogether devoid of interest to the readers of THE MEDICAL RECORD:

Mrs. B——, Laurel Hill, Kings County, was taken with the pains of labor at 4 A.M. on June 8, 1884, and was first seen by her attendant physician some four hours later. At 5 P.M., on the 11th, she was delivered, by the forceps, of an average-sized female child. This was her first confinement. Mrs. B—— is twenty-one years of age, and, without being over robust, had always enjoyed good health. She was married on December 17, 1882, had had no miscarriage, and the period of her pregnancy was otherwise uneventful. On the day next after her delivery she noticed, for the first time, and complained that she had no power of retaining her water. The attending physician took cognizance of the fact, but, in the sequel, on August 5th, finally notified her husband that it would be necessary to remove her to hospital for treatment. On that same afternoon I saw her for the first time, her husband seeking my assistance, having declined, without further consideration, to accede to the suggestion of her whilom medical attendant. On examination I found that the cervix uteri had been split across in the lateral diameter to the level of its entry into the vagina, almost as evenly as one could do it with a knife. The posterior lip was complete, highly congested, swollen from a condition of hyperplasia to perhaps half beyond its normal size, red and angry, was granular degeneration of its endo-cervical mucous membrane. The anterior lip had all but entirely sloughed away, and that, too, level with the roof of the vagina, leaving but a small portion at its left extremity of the size and of the shape of an adult uvula. The condition of this portion was precisely that of the posterior lip. A moderate amount of vaginitis was all that was predicable of the vagina, no lesion in the sense of a solution of its continuity being discoverable. The urethral meatus appeared somewhat patulous. The os uteri would have admitted a bougie of the diameter of a dime. Traction on the posterior cervical lip failed to bring into view any fistulous opening in the uterine walls, but a sudden movement of the patient, while under examination on the table, occasioned a considerable gush of urine through the cervical canal, while at the same time none whatsoever was apparent from the urethral meatus. My diagnosis of vesico-uterine fistula was then definitely decided on, the amount of urine passing through in that one gush precluding the hypothesis of uretro-uterine fistula.

Having explained the state of affairs to the patient's husband, arrangements were at once made for her removal to Greenpoint, within easy distance of my office. Having invited the assistance of two brother practitioners of the neighborhood, I proceeded to operate. This was on August 15th, ten days after my first interview with the patient. The position selected by me was Sims'; I could not have dreamed of attempting the operation in the far more striking, if less convenient, position of Simon. Reasoning *à priori*, I should conclude that in the breech-back (the Steiss-Rückenlage) position the intestines would gravitate forward against the diaphragm in such fashion as seriously to impede the respiratory efforts. I would say further, that in the breech-back position the anterior vaginal wall is so circumstanced as to obviate rather than further the essential principle involved in the employment of Sims' speculum, to wit, the dilatation of the vaginal canal by atmospheric pressure. The first step in the operation was the removal of the uvula-like remnant of the anterior lip, and the vivification of the foundation, so to speak, whence the balance of the lip had sloughed off. The instrument employed was the long, slightly curved—not the angularly curved scissors, nor the bistoury. For the purposes of this particular operation it was most effective. The next step was the amputation of the posterior lip. Now, as between such amputation and an amputation of an entire cervix, the difference is one of degree rather than of kind, and the chief dangers in the path of the latter operation are, it is urged, hemorrhage and cellulitis. Would it not, therefore, it may be inquired, have been better policy to have drawn the posterior lip across the cervical canal, and united it to the vivified base of the anterior lip. My answer is no. To begin with, the dangers from hemorrhage and cellulitis were pretty much the same whether I cut through the attached border of the posterior lip in amputating, or vivified its free borders; and in the second place, as far as the chances of union are concerned, I should not have trusted much to its possibilities, having regard to the posterior lip's advanced condition of congestion and hyperplasia. Having now done with the cervix, the vaginal surface proper, to the extent of four lines in breadth around the borders of the cervix, was next vivified by the denudation of its mucous membrane.

The edges of the wound were now brought together, and six sutures of silver wire inserted. In the passing of the sutures care was taken to enter the needle about three lines from the border of the vivified vaginal portion, bringing it out about the middle of it, re-entering it in the middle of the vivified vaginal surface on the opposite side, and out finally three lines or so from its border, through the untouched vaginal mucous membrane. This procedure gave a thoroughly strong purchase to the sutures, and supplied an extensive surface for apposition

and cicatrization. I may here anticipate my story, and state that a perfect union resulted, and I am disposed to venture on the assumption that, had I left the vaginal mucous membrane untouched, and trusted for union to any vivification of the lips merely, or of the canal of the cervix, the unhealthy condition of those parts must unquestionably have stood in the way of success.

There was, through the operation, no undue hemorrhage, and that point calls for the remark that the inexperienced operator would do well to possess his soul in patience under such a difficulty, and by careful sponging, and if necessary the use of the tampon. secure for the entire operation a thorough view of the field, thus avoiding haphazard, if not dangerous incisions. and defective, unworkmanlike sutures. Before removing the patient from the table, the vagina was well washed out, a piece of lint wet with carbolized oil, one to thirty, applied over the wound, and a tampon, also carbolized, inserted, with the object of giving support to the parts in a possible case of retching or vomiting from the chloroform or other cause. I look upon that as a wise precaution. An opiate was given that night in combination with an astringent mixture of catechu and chalk. The astringent was continued for five consecutive days, and was precisely the same dose as that given on the first evening, save that the quantity of the opiate was materially reduced. I should not on a future occasion follow the policy of confining the bowels, but would rather keep them gently open from the beginning; and I shall not forget that it was not without considerable misgiving that I looked forward to the effect on the cicatricial efforts of the discharge from the bowel of scybalous masses, the product of many days enforced constipation. A little castor-oil was the laxative used, with the best results, on the sixth day. A common male gum-elastic catheter was passed as the patient was put to bed; it was tied in, but withdrawn the next afternoon, the patient being directed to turn gently into the genu-pectoral position when desirous of micturating. The vagina was carefully syringed out with a solution of potassium permanganate, or carbolized water, one to forty, once a day, and the carbolized lint and tampon were renewed. The tampon, however, was discontinued on the ninth day. Some hemorrhage took place on the evening of the sixth, and on the seventh day; it was inconsiderable in amount, though somewhat alarming to the patient. A readjustment of the tampon effectually controlled it. The cause of its occurrence is not quite clear to me, though I have mentally discussed several hypotheses in connection with it. An examination on the ninth day showed a gaping of the wound in its left extremity, with a blood-clot intervening between, and projecting from the edges. Under the circumstances, I thought it well to defer for the present any action toward a removal of the sutures. The patient was however permitted to leave her bed.

It was now for the first time that the effect of the operation in controlling the flow of urine was estimated with a degree of accuracy. Her "water still was coming, but nothing at all like what it used to be." The flow was in reality no more than what might have been conveniently provided against by a napkin, as in the case of the menses. Before the operation no precautionary measures could render it possible for her to leave her house with propriety. Having no misgivings as to the effect of the sutures on the tissues, the more especially after my inspection of them on the ninth day, I contented myself with enjoining for the present the completest local cleanliness, and a daily syringing of the vagina. On the first of September, having placed the patient under chloroform, I withdrew all the sutures save the one next adjoining the still gaping left extremity. It required but a slight pressure over the pubes, and the urine "presented" itself in that opening, becoming a distinct stream on any considerable movement. The retching which supervened a few times under the chloroform invariably brought that about. Two things were at once clear, the one that more sutures, at least one more, were required; the other, that the unclosed portion of the original wound should somehow be further vivified. A vivification of the apposed edges merely would have been a measure of very considerable difficulty, if indeed at all possible, without prejudice to the integrity of the union already attained, and I was opposed to further denudation of the vaginal mucous membrane for the purpose of closing over the opening. Accordingly I determined to employ the fuming nitric acid, applied by a little slat of wood pushed into the troublesome aperture. The cauterizing was effectually done, and an additional suture inserted. A little lint wet with carbolized oil (1 to 40) was the only dressing. The improvement was immediate, and better still, permanent, and yet on the 29th of the month there was still a little dripping, the ghost in fact of its former self. On that day I removed the two remaining sutures, when it was barely possible to discover a minute opening at the extreme end. I was now anxious to avail of Thomas' suggestion of the cutting burr and dentist's treadle, but before I completed my arrangements, for other matters were occupying my attention at the time, the last trace of fistulous opening had disappeared. I last saw the lady professionally on November 15th. There was not then, nor has there been since the slightest trace whatsoever of escaping urine through other than its normal channel. It is, in conclusion, interesting perhaps to note that in no instance was a suture removed before the seventeenth day; that one was suffered to remain *in situ* twenty-eight and another forty-five days. This must necessarily dispose of all doubts as to the availability of the silver suture. The mother and child are both at the present enjoying the best of health, and yet, were it not for the labors of men like Sims and Simon, she might well have "cursed the day on which she was born, and the night on which it was said that a man-child is conceived."

390 Manhattan Avenue, Brooklyn, E. D.

ATROPIA IN SEVERE ELECTRIC SHOCK.

By WM. G. EGGLESTON, A.M., M.D.,
PHILADELPHIA, PA.

The absence from our text-books of suggestions as to the proper treatment of severe electric shock, and the records of three cases—two personal and one in the practice of my father, Dr. J. D. Eggleston, of Hampden Sidney, Va.—in which atropia was successfully used, are my apology for this note.

In his work on "Legal Medicine," Mr. Tidy gives two degrees of shock from lightning, "one producing temporary contraction of muscles and insensibility, from which recovery is possible, and a second, killing directly by producing a condition of nervous and general muscular insensibility." As will be seen by reference to the following cases, after a severe, but not instantaneously fatal shock, there are usually seen sudden insensibility; slow, gasping, and labored respiration; slow, feeble, and irregular pulse, and dilated non-sensitive pupils. (The pupils may be, rarely, contracted and sensitive.) Not infrequently, also, there will be general convulsions.

Case I. *Lightning-stroke.*—This case, the notes of which were obtained from my father, presents three points of interest: 1, As to the position of the patient when struck; 2, the prompt and efficient action of atropia; and 3, as to the sensations of the patient at the time of the shock, and on recovering consciousness. M. L——, twenty-two years of age, was sitting on a bed, the frame of which is of iron, between an open window and a door, playing with a dog. The patient's hand was resting on the dog's head, which was against the left iliac region of patient. A flash of lightning came through the window and struck the patient, the fluid entering, as nearly as can be determined, in the region of the right temple, passing thence to the left iliac region, and out to the floor along the dog. The dog ran out unhurt, and L——

followed him to the door, stopped, caught hold of the frame, did not answer when spoken to, and began to stagger. He was caught while in the act of falling, laid on the floor, and immediately became insensible. While awaiting the arrival of a physician he was, very properly, thoroughly wetted with a large quantity of water. Dr. J. D. Eggleston arrived in twenty minutes. The patient was very cold, insensible, and limp; pulse and respiration very slow, and the pupils widely dilated. There was no mark on his body or clothing. He was immediately put to bed and thoroughly warmed; meanwhile one-eightieth grain of atrop. sulph. was injected hypodermatically. Within a short time after the injection both the respiration and pulse became more frequent; but it was necessary to repeat it in about two hours, and again in two and a half hours. An attempt was made to administer stimulants by the mouth, but the act of swallowing seemed to produce a spasm of the pharyngeal muscles and a general convulsion, and stimulants were administered per rectum. Consciousness returned in about six hours and a half, and the patient immediately asked for his dog. When questioned, he said: "I was sitting on the bed playing with my dog, and a flash of lightning came and I went to sleep." He complained of pain in the head, down the right arm, and in the left iliac region (where the dog's head was resting at the time of the stroke), and of excessive photophobia. On the next day he had a hemorrhage from the bowels, which seems to indicate that the electric fluid had caused a rupture of some small vessel or capillaries in the iliac region, where it passed from the patient to the dog. He also complained of violent headache; but perfect rest and confinement in a dark room produced, in a short time, a decided change for the better in the cerebral and ocular symptoms, though they did not entirely pass away for more than three months. As is well known, a non-fatal lightning-stroke sometimes causes blindness, possibly by coagulating the albumen of the lens (?), as has been suggested. At any rate, it sometimes causes total and permanent blindness, and it was feared that such might be the result in this case.[1]

Case II.—C. K——, twenty-six years of age, received a shock from a dynamo-electric machine on October 8, 1883. He walked about ten steps, said that his arms and hands felt dead, and then became unconscious. When first seen, within ten minutes after the accident, the hands and fingers were strongly flexed; the head was thrown back; the pupils widely dilated and insensible to light; respiration jerky and gasping, shallow and very slow; the pulse slow and irregular, though not very feeble; and the patient was almost entirely unconscious, but sometimes writhing as though in agony. At times, when the head would be thrown back farther than usual, the anterior portion of the neck was markedly bulged and tense. At 8.20 P.M., fifteen minutes after the patient was first seen, one-hundredth grain of sulphate of atropia was given hypodermatically; within twenty minutes the respirations and pulse became more frequent and more regular, and the patient soon so far regained consciousness that brandy-and-water and spir. mindereri were administered every fifteen minutes. The respirations and pulse became irregular again at 9.55, and one-eightieth grain of atropia was injected, with improvement in twenty minutes. Though not entirely conscious, he was able to swallow the brandy and ammonia, which were given every fifteen or twenty minutes. He now steadily improved, until at 12 o'clock he sat up and was then carried home. Beyond a slight weakness and a "curious feeling about the head," there were no unpleasant after-results.

Case III.—A. F. R——, forty-two years of age, a strong and powerfully built man, was seen, January 9, 1884, at 10.05 P.M., a few minutes after he had come in contact with an electric-light wire. He was limp and unconscious; occasional contractions of the hands and fingers; pupils widely dilated; respirations shallow, jerky, slow, and sighing; pulse irregular, very slow, and feeble; head thrown back; occasional shivering. A hypodermatic injection of one-eightieth grain of sulphate of atropia was given at 10.17. The unconsciousness and the pharyngeal spasm were such that the patient could not swallow fluids, and brandy and ammonia were injected into the median cephalic vein. At 11 P.M. the pulse was excellent; respirations still somewhat jerky; hands have contracted twice in twenty minutes. 11.45 —respiration getting shallow again; pulse getting irregular and more feeble; contractions of hands and feet more frequent; one-eightieth grain of atropia, injection of brandy and ammonia. At 12.15 system had fully responded to medicine, and at 1 A.M. had so far improved that brandy and ammonia were administered *per os*, though consciousness had not returned. These stimulants were kept up every twenty minutes in small quantities, until 3.05 A.M., when he sat up and asked for water. For more than a week afterward he complained of photophobia and frontal headache, and of great weakness in his limbs. Within three weeks these had so far disappeared as to give him no uneasiness or trouble. It may possibly be objected that too much stress is laid on the value of the atropia, seeing that brandy and ammonia were also administered in Cases II. and III. But while by no means underrating these stimulants, I cannot regard them so valuable as atropia; for it should be remembered that they were not used so freely in the most severe case (I.), and that although freely and continually used in Case II., they did not keep up the respiration and pulse; and further, that when the bad symptoms returned atropia caused them to disappear in a short time.

Besides the treatment of these cases, attention is called to the symptoms, as persons might be choked while alone. But if the limp condition of the patient generally, and the contracted hands, and possibly feet; the slow, shallow, irregular, and feeble pulse; the contracted pupils (generally, for they may be dilated, or one may be dilated and the other contracted), usually insensible to light; the lowered temperature, and other minor and accidental symptoms, as feeble convulsions, backward position of the head, and pharyngeal spasm be carefully noted, there need be no especial difficulty as to the diagnosis.

Better indications than the above-described symptoms could scarcely be desired for the exhibition of atropia. The predominating symptoms are those of extreme cardiac and respiratory depression. Atropia not only increases the number and vigor of the heart-beats, but "the area over which the pulsations are distributed is enlarged. The number and depth of the respiratory movements are also increased by it. The more rapid action of the heart, the increased respiratory movements, the contraction of the arterioles, result in an increased supply of blood to the periphery, . . . and consequent elevation of temperature. Atropine may be given to counteract a sudden and temporary depression in the heart's action."

New Uses for Apomorphine.—Dr. S. H. Stevenson writes to the *Chicago Medical Journal* of an interview with Dr. Weber, of Darmstadt. "Accidentally," she says, "the conversation turned upon apomorphine, and the Doctor informed me that he had found it a most excellent remedy in chronic asthma, and related a case of some thirty years' standing that had been permanently cured by the administration of one-twelfth grain three times daily, gradually increasing the dose to one-third grain. The result was obtained in about three weeks. The Doctor's brother, who is an obstetrician, had found the remedy very useful in rigid os—not interfering in the least with the normal contractions."

[1] I can find no record of a case in which the blindness, if it resulted, did not follow immediately.

Clinical Department.

SYMMETRICAL DRY GANGRENE OF FINGERS.

Dr. S. C. Clark, of Clayton, N. Y., writes: "I have seen a case of symmetrical dry gangrene of the distal phalanges of both hands recently, and can find no record of similar cases. The gentleman is sixty-three years of age, and suffered from typhoid pneumonia fifteen weeks since, and the gangrenous changes made their appearance soon after. The lines of demarcation made their appearance within six days of the beginning of the disease.

"Will you please inquire through your reliable journal if any others have seen similar cases?"

[In the *Revue de Chirurgie*, Nos. 1, 3, 6, and 9, 1883, MM. Petit and Verneuil, in a series of papers on local asphyxia of paludal origin, describe several cases of symmetrical dry gangrene of the phalanges of either the upper or the lower extremities. The authors speak of the symmetry of the affection as one of its chief characteristics when occurring as a consequence of malarial poisoning and without the intervention of traumatism.—Ed.]

A PERINEUM PIN FOR LACERATIONS.

Dr. S. M. Monser, of San Francisco, Cal., writes, describing his method of adjusting a lacerated perineum. He uses a number of ordinary small safety-pins, either silver or nickel plated. A smooth shirt-button is first passed over the point of the pin and carried back as far as the spring. Then the pin is inserted at a distance of about one-half its length from the rent, and emerges at an equal distance on the other side. A second button is then slipped over the point and the pin is fastened. The points of entrance and exit should be far enough from the line of laceration to insure firm coaptation of the wounded surfaces. The great advantage claimed for this appliance over the ordinary suture is that it causes no strangulation of the tissues, and little if any irritation. Dr. Monser states that he has used it with great satisfaction to himself and comfort to his patient, and has obtained better results with it than with any other form of suture.

A CASE OF OPIUM-POISONING SUCCESSFULLY TREATED BY BELLADONNA.

Dr. David McFalk, of Gouverneur, N. Y., relates the following case: A child, eighteen months old, swallowed some laudanum (the exact amount could not be ascertained), and when seen some five hours later was in a state of profound stupor, bathed in a clammy perspiration, with relaxed muscles, cold extremities, and pupils contracted to a pin-point. The respiration was stertorous, very slow, not exceeding four or five to the minute, and frequently interrupted. The mother had given mustard, alum, and other domestic remedies without producing emesis. One drop of the fluid extract of belladonna was at once injected hypodermically, and repeated every fifteen minutes until three doses had been given, respiration being in the meantime artificially maintained. An improvement was evident after the third dose. The respirations increased in frequency and the intermissions occurred at longer intervals, and the pupils were dilated somewhat. At the expiration of half an hour another drop of the fluid extract was administered hypodermically, and in a short time the pupils became dilated to their normal size, and the respirations increased to eighteen per minute. The child continued to improve, and seemed to be as well as usual the following day. It could not be learned how much laudanum had been taken, but there seems to be little room for doubt that there would have been a fatal termination but for the timely administration of the belladonna in doses just sufficient to antagonize the effects of the opium without producing the symptoms of belladonna-poisoning.

CHRONIC PERITONITIS WITH CYSTIC TUMOR RUPTURING INTO THE INTESTINE AFTER LABOR.

Dr. Victor Dupont, Hospital Steward, U.S.A., San Francisco, Cal., was called to attend a very corpulent woman, forty-five years of age, in her ninth labor. The child was still-born. The woman was at first greatly exhausted and made but slow progress, suffering much from tympanites and abdominal tenderness. On the twenty-third day a large amount (one and one-half gallon) of a serous fluid was passed per rectum. This gave great relief temporarily and the abdominal distention was much reduced. Very soon after, however, the symptoms returned, and the patient sank rapidly and died. The post-mortem examination revealed a chronic peritonitis of long standing. A large cystic tumor of a capacity of not less than a gallon and a half was found united by firm adhesions to the anterior abdominal wall and the small intestines. It communicated with the small intestines, and contained fecal matter. The opening was undoubtedly established at the time that the profuse serous discharge occurred. The other organs were comparatively healthy. Dr. Dupont is unable to say whether the tumor was parovarian, an encysted dropsy, or of some other nature.

BREAKBONE FEVER.

Dr. H. A. West, of Galveston, Texas, sends us some notes of an epidemic of dengue, which has prevailed in that city since August of last year. The epidemic has been severe as regards the number attacked, not fewer, according to Dr. West's estimate, than ten thousand persons having suffered from this painful malady in the course of three months. The writer states that among several hundred cases he saw but one in which there was any glandular enlargement, and this occurred in a child one year old who succumbed to the disease. This was the only case seen by him which terminated fatally. This fact of the non-involvement of the lymphatic glands was peculiar, as the majority of authors mention glandular enlargement as one of the prominent symptoms of dengue. Dr. West conversed with other physicians in Galveston, and their experience of the disease coincided with his in this respect. Another symptom noted by him, upon which most writers are silent, was uterine hemorrhage. This occurred in many women, although they were attacked during an intermenstrual period. The flow usually made its appearance upon the decline of the fever. There were also numerous instances of abortion or premature labor in the case of pregnant women who were suffering from the disease. Most authors lay special stress upon the swelling and pain of the joints, but in Dr. West's cases the pain was most intense in the muscles, especially of the back and limbs. Severe cephalalgia was present in many cases, and frequent complaint was made of epigastric pain. Two patients suffered from obstinate muscular rheumatism continuing for three or four weeks after the subsidence of the fever. Insomnia was pronounced in most cases, and anorexia was complete with very rare exceptions. The tongue was red at its tip and edges, and in most cases thickly coated. Gastric irritability, with nausea and vomiting, were present in many instances for a week or ten days after the fever had disappeared. The temperature at the height of the disease seldom rose above 103° or 104° F. An eruption was present in about half the cases, but in all there was an increased redness of the pharynx. As to treatment, the writer deprecates the use of mercurials in large doses. A gentle saline laxative or castor-oil was all that was required in most cases. Hot mustard foot-baths, sinapisms to the nucha and epigastrium, and turpentine stupes to the back were found useful. Aconite, belladonna, and liquor ammonii acetatis mitigated the fever. The bromides and hydrate of chloral helped to relieve the headache and induce sleep, but opiates were

found of greater value and they also were efficacious in quieting the gastric irritability. A combination of Dover's powder with muriate of pilocarpine was found to act well, the free diaphoresis thereby induced affording great relief. Stimulants in the form of light white or red wine were of great service in restoring the tone of the stomach. It was noted that previous attacks did not confer exemption, many persons being seized who had suffered from the disease in previous years.

THERAPEUTIC APPLICATIONS OF COCAINE HYDROCHLORATE.

We are constantly in receipt of communications from correspondents calling attention to the efficacy of cocaine in hyperæsthetic and irritable conditions of the mucous membranes. The following cases are reported :

Irritable bladder.—Dr. Sara E. Post, of New York, writes : "Two weeks ago I employed cocaine for an irritable bladder, with almost constant micturition, which four grains of the extract of opium, given per rectum in the course of twelve hours, did not control. By means of the Cushier intra-uterine syringe ten to fifteen drops of the two per cent. solution of cocaine were injected, so as to bathe the neck of the bladder and the urethra over its whole extent. The relief was immediate. The patient did not micturate for an hour after the application, and not more frequently than once in forty-five minutes during the night. The previous condition did not recur."

Asthma.—Dr. Post relates another case of a woman, sixty years of age, who had suffered from asthma for many years. She presented herself at the clinic for general medicine at the New York Infirmary during an attack. Examination showed a catarrhal condition of the naso-pharyngeal mucous membrane, and thinking that the dyspnœa might be the expression of a nasal reflex, Dr. Post painted the mucous membrane of the nose and throat with a four per cent. solution of cocaine. Within ten minutes the spasm was relieved and respiration became easy and inaudible. The patient was afterward treated with local applications of tannin and glycerine, and the asthma has not returned. This result would seem to argue well for the use of cocaine in the paroxysms of asthma occurring in hay fever.

Pruritus vulvæ.—Dr. Sarah J. McNutt, of 238 East Thirteenth Street, writes : "I have under my care a patient who suffers from an exaggerated pruritus vulvæ, associated with a peculiarly atrophied condition of the parts. All of the usual remedies had been tried with but little relief at any time, and frequently with apparent aggravation of the trouble. This patient came to me a few days ago meditating upon self-destruction, her agony was so great. A four per cent. solution of cocaine painted over the parts gave almost immediate relief, the patient remarking, 'I have now no sensation, not even the sense of soreness, from the rubbing and scratching which has been done.' The physician's satisfaction was almost equal to that of the patient, her treatment had been such a care."

HEROIC DOSES OF CALOMEL IN THE TREATMENT OF CHOLERA.

Dr. Thomas J. Henderson, of Woodville, Miss., advocates the employment of calomel, given with an unfaltering aim in large and frequently repeated doses, in the treatment of cholera. He writes : "During the prevalence of cholera from 1848–55, and since, I have used calomel as the principal remedy, and whenever I have been able to get it to act on the liver (which it will do in nearly all but the most malignant cases, if given in large and frequently repeated doses), I have had the satisfaction of seeing my patients recover." He suggests that the remedy may not only act as a cholagogue but also as a microbicide. He relates a case occurring in May, 1849, in which he was called to see a negro, living in East Baton Rouge, sick with cholera. The patient was lying on a cot in a little cabin surrounded by water, he was vomiting, passing rice-water discharges from the bowels, suffering agony from cramps, with cold shrivelled skin, weak pulse, and great prostration. *Fifty grains* of calomel were given at once in a little sugar moistened with brandy, while mustard plasters were extensively applied to the surface, and hot applications made quite freely around the body and extremities. When the treatment was begun the patient was passing copious rice-water discharges every twenty or thirty minutes. The calomel was repeated in equal or larger doses after every second or third evacuation. When three or four doses had been taken the vomiting ceased, the cramps diminished in intensity, and the alvine discharges became less frequent and much smaller. In about twelve hours bilious stools began to make their appearance, and the calomel was then discontinued, to be resumed only in case the cramps, vomiting, or rice-water discharges should return. In a few days the patient was again on his feet, though, of course, very weak, and eventually recovered. Dr. Henderson does not say what was the total amount of calomel given, but it could not have been far from one ounce.

A SUCCESSFUL CASE OF TRACHEOTOMY FOR DIPHTHERIA.

As illustrative of the good results of early tracheotomy, even in an unpromising case, Dr. H. H. Lee, of West Stewartstown, N. H., sends the following notes :

"L. K——, two and one-fourth years of age, previously healthy, was attacked with diphtheria about November 7th, the tonsils and posterior pharynx being then covered with a false membrane. Breathing was slightly stridulous. Dr. Ward, who first saw the case, gave calomel, ipecac, brandy, and lime-water inhalations, with concentrated nourishment. The following day the laryngeal symptoms were marked—feeble, crowing respiration, episternal and abdominal retraction during inspiration, and a hoarse laryngeal cough. The tonsils and posterior pharynx were covered with a thick grayish membrane. There was also a profuse diarrhœa, accompanied with considerable abdominal pain and distention. The child persistently refused nourishment. It was decided, on consultation, to perform tracheotomy should no improvement occur within twenty-four hours, and, no tracheotomy tube being at hand, one was immediately telegraphed for. The breathing became more and more labored, the signs of carbonic-oxide poisoning were growing evident, and death from suffocation seemed imminent. As soon, therefore, as it was light, on the morning of November 9th, the patient was anæsthetized, and the trachea was opened in the usual way. A silver wire was passed through each border of the tracheal wound, and the opening maintained by fastening the wires at the back of the neck. Just before the completion of the operation the child was apparently moribund, no radial pulse was perceptible, and respiration had ceased. As soon as the trachea was opened, however, inspiratory efforts were excited, and the patient rallied under hypodermic injections of brandy and ether, artificial respiration, and the application of dry heat. The tube arrived in the course of the forenoon, and was then inserted. In a short time after the operation the patient, who had previously refused all nourishment, would swallow with avidity all the milk and brandy that was offered it. The temperature of the room was maintained at about 70 , and the atmosphere was kept charged with vapor. The child was in a critical condition during the two succeeding days, but then began rapidly to improve, and eventually made a good recovery."

Medical Society of the State of New York.—The attendance at the coming session will be unusually large.

Progress of Medical Science.

The Introduction of Inorganic Material does not induce Tuberculosis.—When Koch first announced to the world his discovery of the tubercle bacillus, and gave an account of the experimental evidence which had convinced him of its essential etiological relation to the disease tuberculosis, it was natural that conservative physicians should demand additional evidence and confirmation from other sources before accepting his conclusions, notwithstanding the reputation which he had already established as an expert and conscientious investigator. Hence Dr. George M. Sternberg was led to study the *modus operandi* of the bacillus in producing tuberculosis, and ascertain whether its pathological power resulted from its simply acting as a mechanical irritant or depended upon specific physiological characters peculiar to it. The result of his investigation, which was made in the biological laboratory of the Johns Hopkins University, appears in the January number of *The American Journal of the Medical Sciences*. He injected into the peritoneal cavity of a number of rabbits, thoroughly sterilized, powdered glass and marine blue, taking every precaution to avoid the dangers and possibilities of accidental infection, and the results gave no support whatever to the claim that tuberculosis may be induced by the presence of finely powdered inorganic particles, or to the view that the tubercle bacillus induces tuberculosis by acting simply as a mechanical irritant.

The Secretion of Bile.—Dr. D. Baldi, of Florence, has recently undertaken a series of experiments on the process of secretion of the bile, in which he has endeavored to ascertain whether it takes place in a uniform manner in accordance with the presence or absence of food in the alimentary canal, and whether it varies materially with the nature of the food. A biliary fistula was first made, the ductus communis choledochus being ligatured so that no bile entered the duodenum. Dr. Baldi found that there was a singular irregularity in the quantity of the secretion formed, distinguishing the function of the liver from all other digestive secreting organs. Not only was there great variation in the absolute quantity secreted, but the composition of the bile differed remarkably at different periods after a meal. Speaking broadly, in an animal that has been supplied with food, there is an augmentation in the total quantity of bile secreted in the course of some hours as compared with the quantity secreted in the same time by the animal when fasting. It is not possible, however, to fix the time at which the secretion of bile after food is at its maximum; indeed, it is even possible that the maximum may be attained during some one hour when the animal is fasting. Different kinds of food, starches, proteids, fats, and mixed foods, have no appreciable effect on the quantity or quality of the bile. If we consider, in addition, that unlike the other secretions which are poured into the intestinal tract, the bile continues to be secreted in prolonged fasting, as has been demonstrated by various experiments, we shall be led to the conclusion that this fluid, from a physiological point of view, has more analogy with urine than with the other digestive fluids. In a second series of researches, in which the effects of reputed cholagogue drugs were investigated, Dr. Baldi is not in accord with either Röhrig or with Rutherford. Röhrig found that colocynth was the most active cholagogue; then, in succession, jalap, aloes, senna, and rhubarb. Rutherford considered the order to be—podophyllin, rhubarb, aloes, colocynth, senna, and other drugs. Baldi experimented with podophyllin, rhubarb, jalap, sodium phosphate, pilocarpine, and Carlsbad water, and, from his results, feels inclined to doubt altogether the cholagogue value of all these substances. He admits, however, that the presence of a biliary fistula seriously interferes with the action of remedies. Dr. Baldi undertook still another series of experiments, to determine whether bile injected into the blood was excreted by the liver. The animal employed was the dog. The bile injected was that of the ox deprived of mucus. Dog-bile is brown; ox-bile green. Almost immediately after the injection of ox-bile the color of the bile secreted by the dog became green.

Erysipelas as a Complication of Pregnancy and Labor.—In *The American Journal of the Medical Sciences* for January Dr. G. H. Balleray records two cases of labor with concurrent erysipelas without untoward result. He points out that the management of labor in the case of a woman suffering from erysipelas does not materially differ, other things being equal, from the management of a case of normal labor. The accoucheur should abstain from frequent vaginal examinations during labor; and such examinations as are necessary should be made with *clean* hands. The placenta should, if possible, be delivered by Credé's method; thus avoiding the introduction of the finger or hand within the genital canal. A full dose of ergot should be given after the delivery of the placenta; and the uterus should be gently manipulated until it is *firmly* contracted. In the after-treatment the nurse should be forbidden to touch the genitals of the patient, without having previously washed her hands thoroughly with *hot* water and soap. The use of antiseptic vaginal injections should be commenced within twelve hours after delivery, and continued as long as there is any indication for their employment.

Medicine in India Two Thousand Years Ago.—Professor H. Kern, of the University of Leyden, the distinguished author of many works on Oriental subjects, has lately published a History of Buddhism in India. Of this a translation into German has been published at Leipsic, from which *The Medical Press*, December 3, 1884, extracts the following concise but complete account of the state of medical science in India about two thousand years ago, as gathered from the set of Buddhist works called the Mahavagga: "In sickness the religious orders might take butter, clarified butter, honey, and sugar, but only as medicine. The Lord Buddha also permitted the medicinal use of five fat substances, namely, bear's grease, fish oil, guinea-pig fat, pork suet, and asses' fat; also of the different roots which take a very important place in the Hindu Pharmacopœia, such as ginger, turmeric, calamus, and andropogon. The preparation and use of infused herbs or teas, the use of curative leaves, fruits, and resins, of salt powder, eye-salve, even of raw flesh and blood, the employment as remedies of snuffs and of pipes for inhaling the smoke: all these things were allowed by Buddha. The medical system even included the following cures: Salves for rubbing in, three kinds of cupping-glasses, many sorts of vapor-baths, plunge-baths, bloodletting, the use of lancets for cutting out sores, corrosive fluids, gargles, bandages, means for cleaning wounds, corrosive alkalies, purgatives, clysters, etc. This catalogue is sufficient to give one some idea of the state of Indian medicine at the time in which the canonical writings (the Mahavagga) from which the details are taken were composed." In another passage Dr. Kern mentions that the ancient Hindus smoked various sorts of herbs in pipes and cigars as we do tobacco, and that pipes are described in the most ancient Indian works on the art of medicine.

A Contribution to Jacksonian Epilepsy and the Situation of the Leg Centre.—In the January issue of *The American Journal of the Medical Sciences* Dr. William Osler, of the University of Pennsylvania, records the history of an instructive case of Jacksonian epilepsy. The main points of difference between that disease and true epilepsy are—the slow onset, local in character, beginning in, or in mild attacks confined to, one limb or a single group of muscles; the gradual extension until the side is involved, or, in severe attacks, the entire body; loss of consciousness late, not early and sudden, as in

true epilepsy; and, lastly, the muscular contractions are clonic. His case lasted over fourteen years, the convulsions beginning in the left hand, at first monobrachial, then extending to the leg, afterward becoming unilateral, and finally general; at first without loss of consciousness. For the first nine years of the illness there were remarkable intermissions, lasting for six or seven months, once an entire year. Six years after the onset the left leg got weak and stiff. For four years—the tenth, eleventh, twelfth, and thirteenth of the illness—the seizures were frequent. During this period there were six weeks of unconsciousness in which the spasms were very frequent, fifty to eighty in the day. Ten months prior to the final attacks there was freedom from convulsions. The intellectual faculties were unimpaired. The case is unusual in the limitation of the lesion to the ascending frontal convolution and to its fasciculus of white matter, scarcely involving the gray substance, which is commonly affected in cortical epilepsy. The accurate localization and the remarkable absence of tissue-changes in the immediate vicinity give the case the nature of an exact physiological experiment. With this limited lesion of the motor area there was permanent paralysis, with contracture of one extremity and epileptiform convulsions. Another feature of interest in the case is the light it throws on the situation of the leg centre. The fibrous mass was situated entirely within the anterior part of the paracentral lobule, limited in extent, confined chiefly to the medullary fibres of the superior frontal fasciculus, and only touched the gray matter in places. A point to be referred to is the absence of the paralysis of the leg for the first six years, for, if the convulsions and monoplegia were caused by the same lesion, how explain the late onset of the latter? From the fibroid state of the tumor it might reasonably be inferred that it was originally larger and had shrunk, but the absence of puckering on the surface and the way in which the margins merged with the contiguous parts make it probable that the growth was always small, so small in fact that at one period of its development it may have caused sufficient irritation to induce the convulsions, and yet at the same time not involve the special fasciculi of white fibres to the extent of producing weakness of the leg, or monoplegia.

The Treatment of Diarrhœa by Resorcin and Salicylic Acid Dissolved in Castor-oil.—Dr. Bogush discusses the treatment of acute and chronic cases of offensive diarrhœa accompanied by high fever, and sometimes delirium, on the one hand, and by the presence of enormous quantities of micro-organisms in the fæces, on the other. The author thinks that a severe aspect of similar cases may be dependent upon the self-poisoning of the system by ptomaines originated in the intestines. Hence, the rational treatment of the diarrhœa must consist in a rapid removal of the contents from the intestines, and simultaneously in destroying the microbes. As the author's experience proves, this end is most successfully obtained by the administration of a solution of resorcin in castor-oil. For the adult his formula is this: ℞ Resorcini puri, ʒj.; olei ricini fervidi, ℥v. Solve. To be taken at once. To children he administers eight grains of resorcin in a corresponding quantity of castor-oil. To disguise the odor and taste of the latter he advises to mix the solution with a tablespoonful of beer or stout. Of his numerous cases treated in this way, only one did not yield to resorcin, but rapidly recovered after the administration of twenty grains of salicylic acid dissolved in a tablespoonful of hot castor-oil. Resorcin proved equally successful in similar cases in Dr. Ikoff's practice. The author proposes to try the same plan of treatment in cholera. In conclusion he adds that when observing an epidemic of cholera in Egorievsk in 1871, he obtained the best results from hypodermic injections of morphia and internal use of castor-oil with opium. Dr. Sprimon, from his independent observations, testifies to the value of castor-oil in cholera. In choleraic epidemics in Voroneje in 1866 and 1868, recovery followed in every case where castor-oil had been administered before the asphyctic stage of the disease. Quinine proved not only useless, but even harmful, especially in the asphyctic stage. In the latter, the best results are given by free and often-repeated subcutaneous injections of brandy, tincture of musk, ethereal tincture of valerian, ether, spirit of camphor, and other stimulants.—*London Medical Record*, November 15, 1884.

Double Infantile Spastic Hemiplegia.—In the January number of *The American Journal of the Medical Sciences* Dr. S. J. McNutt reports a case of double infantile spastic hemiplegia, with carefully recorded notes of the post-mortem appearances, illustrated with seven cuts exhibiting the lesions found. This is believed to be the third, or, at the most, the fourth case of its kind upon record. Yet these cases do not appear to be so very uncommon, since four others presenting similar symptoms are known to be now in New York City. As a distinct condition, even simple infantile spastic hemiplegia has but lately received attention in text-books. For this reason, and on account of the difficulty of obtaining any comprehensive information on the subject, the collection of facts and theories presented in Dr. McNutt's paper is quite valuable, and will doubtless lead to a further study of this interesting condition. The author has collected and tabulated thirty-four cases in which autopsies have been made, and each of them presented atrophy of the cerebral cortex near the fissure of Rolando. The subjects of infantile spastic hemiplegia may live to old age. The inception of the disease, however, always dates back to early childhood, or to intra-uterine life. At whatever age seen, its victims are characterized by more or less complete hemiplegic motor inability, atrophy, and contractures, with or without aphasia, monosyllable utterance, dysphagia, dyspnœa, and idiocy, the latter being especially characteristic of the double affection. The etiology of infantile spastic hemiplegia has been defined as primitive defect, arrest, encephalitis, and hemorrhage. Clinically the cases may be divided into three classes: those in which the inception of the condition precedes birth, those in which it occurs after birth, and those of which parturition is the cause. The paper concludes with a careful study of the differential diagnosis and treatment.

Poliomyelitis Anterior in Adults.—Dr. Gustavus Eliot, of New Haven, records, in *The American Journal of the Medical Sciences* for January, a carefully noted case of poliomyelitis anterior occurring in an adult. The progressive development of muscular weakness, unattended by febrile symptoms, but accompanied by diminution of the size of the limbs, by abolition of the patellar tendon reflex, and by sensations of numbness, yet without loss of tactile sensation, and without interference with the function of either the rectum or bladder, rendered the diagnosis clear and indisputable. A large proportion of the reports of cases which have been published contain little or no information concerning the details of treatment, and in many others the multiplicity of drugs prescribed renders any reliable conclusions in regard to the effect of each almost impossible. Bromide of potassium, belladonna, strychnia, ergot, and iodide of potassium have been most often employed, and most praised. Counter-irritation, baths, rubbing and exercise, and electricity are also included as important elements in most plans of treatment. From a careful study of the results of various plans of treatment, as reported by various observers, Dr. Eliot deduces the following conclusions: 1, Counter-irritation and ergot should be employed early in every case; 2, massage and electricity should be used as soon as there is any evidence of improvement; 3, little, if any, effect can be expected from iodide of potassium; 4, belladonna and the bromides should be used only with extreme caution; 5, strychnia should be entirely avoided.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 31, 1885.

USE THE EPIDEMIC FUND.

IN our last issue we urged the appropriation by Congress of the funds necessary to enable the National Board of Health to devise and put in operation the measures necessary to prevent the introduction of cholera into the United States. Since that writing the Committee on Public Health of the House, Hon. Lewis Beach, of New York, Chairman, has recommended the appropriation of $25,000 to the National Board, and an additional sum of $500,000 to be used at the discretion of the President. The Committee took a very sensible view of the situation, and decided that there was not time during this session to consider new health bills, and that it was the part of wisdom to empower the existing board to act. But commendable as this action of the Committee undoubtedly was, the emergency is not thereby met. In the ordinary course of affairs, if such appropriations are passed, the funds are not available before the 4th of March. Meantime, the season is fast approaching when the first cases of cholera, the *avant couriers* of the epidemic, make their appearance among the immigrants. In our opinion, if adequate preventive measures are to be planned and put into successful execution against the present threatened invasion, the whole machinery must be in full operation, at the latest, as early as the 1st of April. Now, what does this preparation imply? First, that the National Board of Health shall plan and adopt the measures which are to be relied on to prevent the introduction of the cholera contagion. Those measures cannot be matured in a week, nor in twice that time, by the most experienced sanitarians in the country. They must necessarily involve interests of the highest importance to the travelling public, to the steamship companies, and to the foreign commerce of the entire country.

To perfect rules and regulations governing such vast public and private interests, so as better to protect the country from a pestilence, and yet interfere the least possible with the rights of private individuals and corporations, will require weeks of considerate discussion and wide consultations with all parties affected by, or interested in, such measures. And when the scheme of prevention is perfected, if it is organized as modern sanitary science demands, it will involve the creation of a series of official inspections of a minute and yet comprehensive character, so related as to form a harmonious plan of surveillance of ocean travel and commerce, which must intercept the contagion of cholera in whatever form it is being transported. This official inspection must begin in the foreign port, must be careful and searching at sea, must be reinforced at all our seaport quarantines, must extend along the Canadian frontier, and must finally end at the terminus of every great trunk railroad of the United States.

It will be seen that even after these measures of prevention are adopted, it will require time to organize and set this machinery in motion. The officials who undertake the duties herein outlined must be trained and reliable men who have been carefully selected for their individual qualification for the special work they are to perform. Steamship companies must be conferred with, and a plan of co-operation decided upon. The local quarantines must all be visited, and strengthened at all points where they are defective. The Canadian health authorities, who have always shown a most admirable spirit, and a desire to aid in the prevention of widespread epidemics, should be conferred with and brought into active co-operation. The trunk lines of railroads, which carry the great bulk of immigrants, should be consulted and induced to co-operate with the steamship companies in carrying out and rendering effective the methods proposed.

It will undoubtedly be alleged that the scheme of preventive measures above outlined is unusually comprehensive, and that their execution will prove expensive. Both statements are true. We propose nothing less than the *prevention* of an epidemic of cholera in this country. No half-way measures, as the past history of the pestilence proves, can accomplish that result. Every avenue of approach is to be guarded, all along the lines of travel, by a large force of skilled officers. Is the object sought worth the effort and expense? We believe it is. An invasion of cholera means the death of thousands of the laboring people, the occurrence of tens of thousands of cases of sickness, and the loss of millions of dollars in business. In our view prevention at any cost is comparatively cheap.

We repeat, the National Board of Health should meet at once and continue in session until its measures are not only matured, but put into effective operation. It is stated that it has no means, even to pay office rent, owing to the failure of Congress to make an appropriation last year. If that is true, there is still the Epidemic Fund, to be used at the discretion of the President in the event of a threatened or actual epidemic. There is no reason why the expenses of the Board should not be defrayed out of that Fund. President Arthur knows well what an epidemic of cholera means to the health and business interests of New York. Let us ask him, in all seriousness, if cholera is not sufficiently threatening to make it incumbent on him to use that Fund to prevent the invasion.

Profoundly impressed with the threatening attitude of cholera, and the power of preventive measures, wisely matured and vigorously executed, to protect us from the pestilence, we can but regard every day's delay on the part of the general Government to employ all the means at its command to meet the increasing emergency as an unpardonable trifling with the lives of the people and the future business of the country.

THE PHYSIOLOGY AND SURGERY OF THE THYROID GLAND.

An unusual amount of attention has been devoted, during the past year or two, to the subject of the thyroid gland. On the one hand, the surgeons have been industriously, and in a measure successfully, attempting its extirpation for disease; on the other, physiologists have been removing the gland in animals, with a view to obtaining a more definite knowledge of its functions. Already some very striking observations have been made, and important results foreshadowed.

Some two years ago, the attention of Dr. Kocher, a German surgeon, was called to the fact that after total extirpation of the thyroid gland in man, peculiar symptoms set in, and finally a set of phenomena which he called "cachexia strumapriva," and which much resembled that of myxœdema, was developed. His observations were confirmed by those of Reverdin, Julliard, and other surgeons. Quite recently, Professor Horsley, of the Brown Institute, London, extirpated the thyroid glands of monkeys. He found that in these animals a condition resembling the "cachexia strumapriva" of Kocher, the "myxœdema" of Ord, and the "cretinoid state of old women" of Gull, was produced. But in his cases the condition came on within five or six weeks, the animals rapidly dying from the effects of the induced disease. The symptoms were those of severe nervous disturbance, commencing with tremors and followed by paresis and hebetude; there also developed an oligæmia and leucocytosis; mucin was found in the blood, subcutaneous tissues, and salivary glands, and there was a puffiness of the face and a subnormal temperature.

Mr. Horsley concluded that the gland has much more important functions than has been supposed, and that these are: first, to excrete mucin; second, to manufacture red blood-corpuscles.

The publication of Kocher's observations has stimulated continental physiologists to great activity.

Dr. D. G. Zesas, of Bern (*Langenbeck's Archiv*, Bd. xxx., Heft 2), as the result of experiments upon dogs and cats, reached the conclusion that the thyroid was a gland having a certain hæmatogenous function, like the spleen, but that it was also, as Liebermeister has suggested, an important regulator of the intracranial circulation. The animals upon which he operated all died within a few weeks, and not, he claims, as the result of the operation. He always found at the necropsy marked cerebral anæmia, and their dull, sleepy, weak, and progressively marasmic condition he attributes to this cerebral disturbance.

Soon after the appearance of Zesas' article, Professor Schiff contributed the results of a similar study (*Archiv f. Experiment. Pathologie u. Pharmak.*, Bd. xviii., Heft 1 u. 2). The animals (dogs and cats) operated upon all died in from four to twenty-seven days. They also became dull and marasmic, but Schiff noted various sensory and motor disturbances, such as itching, paræsthesia, tremors, and paralysis. He noted also a brain anæmia upon post-mortem, but he concludes that the thyroid has some controlling effect upon the nourishment of the central nervous system, and explains upon this hypothesis the symptoms following its extirpation.

Dr. J. Wagner, of Vienna (*Centralbl. f. Deut. Med. Wissenschaft*, July 26, 1884), extirpated the thyroid gland in dogs, cats, and kittens. Tremors, clonic spasms, difficulty in locomotion, dyspnœa, increased nervous irritability, and anæsthesia were observed. The animals died in from two to four days, from which one must conclude that the operation had more to do with the symptoms, than the absence of the gland. Two animals, from which only half the gland was removed, remained healthy.

Sanquirico and Canalis (*Archive Italienne de Biologie*, Bd. v., Heft 3, 1884) extirpated the thyroids of twelve dogs. In two cases half the gland was removed at one operation, the remainder at a later operation, after the first wound had entirely healed. All the animals died within from four to sixteen days subsequent to the treating of the wounds. The phenomena observed were much like those described by Schiff. Vertigo and ataxic movements were noticeably present. The post-mortem examination revealed marked anæmia with some œdema of the brain. Examination of the blood revealed only "slight and variable modifications," thus contradicting in a measure the observations of Horsley and Zesas. Sanquirico and Canalis agree with Schiff in the view that the thyroid stands in some important relation to the nutrition of the nervous system.

The fact that after extirpation of the thyroid in animals, death occurs within from one to four or five weeks, naturally suggests the idea that this mortality may be due to the severity of the operation, or to some mechanical trouble caused by an operation in a place so rich in vessels and nerves as the anterior part of the neck. This was the conclusion arrived at practically by Kaufmann (*Archiv f. Exp. Path. u. Pharm.*, Bd. xviii.), as the result of his experiments in extirpating the thyroid glands of dogs. He first employed the operation by median incision, with simultaneous total extirpation of both lobes. Two strong dogs thus operated upon died respectively in one and in three days, from hemorrhage and septicæmia. He then removed the lobes separately by lateral incisions, waiting until the first wound was healed, before the second operation was undertaken.

The whole of the thyroid was removed from three dogs in this way. One of these animals contracted the distemper (*Staupe*) and died in five weeks. The other two remained healthy. Kaufmann claims that these experiments contradict and subvert the conclusions of Zesas and Schiff. Dr. Zesas says, however, that he has seen Kauffmann's dogs in the Zurich Pathological Institute, and they are extremely meagre and emaciated. He cannot deny that they have lived already for nine months, but he denies that his own animals died from the direct effects of the surgical operations, since death occurred in some cases weeks after the healing of the wound.

The view of Kaufmann, however, is in a measure supported by others, who also deny the serious results of thyroidectomy which Kocher describes. Professor Bardeleben, of Berlin (Medical Record, May 12, 1883, p. 523), states that he has removed the thyroid gland from a dog, with no bad result, and that he has successfully removed diseased thyroids of adults in two cases. He believes that the cachexia which Kocher calls attention to, would have appeared in any event, and was part of the disease which caused the goitre. Wölfler, of Vienna,

apparently disagrees with Kocher's view also. In a paper upon the surgery of the subject (*Deutsche Medizinische Wochenschrift*, April, 1883), he says, that there have been only five deaths out of sixty-eight cases operated upon by Billroth in the past six years.

In summing up the results of present observation, we are led to the conclusion that it is at any rate safer to lean toward the views of Kocher, Horsley, and Schiff, as to the high functional importance of the thyroid gland. It should never be removed except as a very last resort, and then some parts of the tissue or capsule should be left. As to its function, the theory that it is an important regulator of the cranial circulation, is fanciful and improbable. The view that it is a hæmatogenous organ is well supported, while its alleged relations to the excretion of mucin and the nutrition of the nervous system are still *sub judice*.

THE DISCOVERY OF THE SPECIFIC GERM OF DIPHTHERIA.

At a recent meeting of the Clinical Society of the New York Post-Graduate School, Dr. M. Putnam-Jacobi called attention to the very elaborate and possibly epoch-making investigations, regarding the parasitic nature of diphtheria, which have been made by Löffler. It is well known that despite the immense amount of labor which has been expended in studying the pathology of diphtheria, the actual relations of micro-organisms to this disease have, up to the present time, remained undetermined. Most observers who have presented the claims of a micro-organism have identified it with certain micrococci found in the diphtheritic tissues. A few, like Eberth, of Zurich, have referred the disease to a bacterium, while the weight of critical opinion, up to the time of Löffler's experiments, has been against the view altogether of their being a specific pathogenic organism.

Löffler sums up the results hitherto obtained from investigations as follows: All observers have found bacteria in diphtheritic pseudo-membranes, although many have contented themselves with searching for it by means of the dilaceration method, which prevented the exact relations of the tissues from being ascertained. In the majority of cases the bacteria described have been micrococci, usually in colonies, and these nearly always on the most superficial part of the membrane. Only occasionally have they been found in the lymphatics of the affected parts; still more rarely (Letzerich) in internal organs. To examine these the modern resources of aniline staining, Abbé's condenser, and oil immersion lenses have, so Löffler asserts, been only insufficiently employed. Cultures have been made in fluid media, and thus it has been impossible to isolate from each other the different species of bacteria, of which every diphtheritic pseudo-membrane contains several. In the coincident evolution of these different species, the physiological action of each becomes neutralized, and even the development of some completely hindered by that of others. This circumstance accounts for the negative or atypical results of inoculation with the products of such fluid cultures; and similarly, for the uncertainties consequent upon inoculation with fragments of the membrane itself, as in the experiments of Satterthwaite and Curtis.

Löffler's own experiments were divided into three parts:—

1. Histological examination of the tissues of patients who had succumbed to diphtheria (tonsils, pharyngeal and laryngeal mucosa, internal organs).

2. "Pure" cultures on solid substances of two species of bacteria discovered during above examination: namely, micrococci in chains and a species of bacillus.

3. Inoculation, subcutaneous, muscular, corneal, or tracheal, of products of such cultures, from the fourth to the twenty-fifth generation, upon several species of animals (mice, guinea-pigs, rabbits, pigeons).

Of the two species of bacteria above referred to, the micrococci seem to be identical with the micrococci observed and studied by previous investigators. These he cultivated and used in inoculations.

He finally concludes regarding them, that: "Since the chained micrococci excited in no animal an artificial disease even resembling diphtheria: since they were only observed in a limited number of cases of human diphtheria, and then associated with bacilli: since they exactly resemble the micrococci of erysipelas and other infectious diseases, they are only accidental complications of diphtheria. They may, however, sometimes excite a disease resembling it."

Cultures were then made with the other micro-organisms, the bacilli, which were isolated and cultivated upon stiffened blood-serum. They do not develop on the meat-water-peptone-gelatine, partly at least because this softens at a temperature about 20° C., and a temperature higher than this is essential to the development of this species of bacilli. A temperature of 60° C. kills them. The duration of their life seems to be about three months.

The result of experiments, conducted with these new bacilli, is summed up by Löffler as follows: They were found in thirteen cases of diphtheria with fibrinous exudation; they lay in the oldest part of the membrane and penetrated farther toward the tissues than the other bacteria; products of the cultures of them, carried to the twenty-fifth generation, when inoculated under the skin of guinea-pigs and small birds, kill the animals, after the production of a whitish or hemorrhagic exudation at the point of infection, and extensive subcutaneous œdema. The inner organs remain intact, as do those of diphtheritic patients. Pseudo-membranes were generated by inoculation of the trachea of rabbits, chickens, and pigeons, or of the vagina of guinea-pigs. There are then also evidences of several vascular lesions, manifested by hemorrhagic œdema, by hemorrhages into lymphatic glands, and effusions into the pleural cavity. The bacilli, he says, have thus the same effects on the animal organism as the diphtheritic virus.

The bacillus which would thus suddenly assume so much of importance to the human race is considered to be identical with the bacillus of diphtheria described by Klebs at last summer's International Medical Congress; and it is a significant fact that two experienced investigators should thus have arrived independently at similar conclusions. The micro-organisms in question are motionless rods, partly straight, partly curved, about the length of the tubercle bacillus but double its breadth, coloring intensely with methyl blue potassa solution, discoloring again with diluted iodine, except at the two ex-

tremities. They are found deep in the tissues, where they are supposed to develop a poison which decays the surrounding tissues, paralyzes the blood-vessels, causing congestions, exudations, and finally paralysis of nerve-centres and death.

Such are the main facts regarding the alleged pathogenic organism of diphtheria. Undoubtedly, Löffler and Klebs have secured for it a greater weight of positive evidence than has ever been obtained previously for a specific diphtheritic germ. Perhaps the only points which are open to criticism are these: Löffler confesses that in certain typical cases of diphtheria the bacillus was not found, and he assumes that here they have died and been eliminated. It can hardly be doubted, however, that the tissues and juices in these cases would have proved infectious. But how could they be so with the specific germ absent? Again, it may be asked whether the disease produced by inoculation of these bacilli into animals was surely, and always, identical with the diphtheria of man. Further experiments of Satterthwaite and Curtis seem to show that lower animals cannot be inoculated with diphtheria, and their conclusions cannot be swept away by saying that other germs neutralize for animals the specific action of the bacillus, when it is an established clinical fact that they do not do this for man. On the other hand, however, it has been shown by some experimenters, and quite recently, by Dr. C. J. Renshaw (*British Medical Journal*, January 3, 1885), that sometimes true diphtheria can be inoculated in lower animals.

THE ACHIEVEMENT OF THE PENNSYLVANIA RAILROAD COMPANY.

In a recent article on "Control of Vision," Dr. Jeffries, of Boston, calls attention to the entire failure in Connecticut, and the partial failure in Massachusetts and in England, to obtain efficient legislation to compel railroads to discharge employees with visual and aural defects. Dr. William Thomson, of Philadelphia, in a later article in the *Popular Science Monthly*, explains this failure and shows how the Pennsylvania Railroad, alone of all companies, has succeeded in subjecting its employees to physical tests. The difficulty with attempts at legislation so far has been that the advocates of the tests would compel railway companies to have expensive examinations made by medical men, which examinations would result in a decimation and demoralization of the force. To the Pennsylvania Railroad Company and Professor Thomson belong the credit of devising and putting into practice a scheme by which the tests could be applied quietly, economically, and effectively. Dr. Thomson invented instruments for the examination of the color-sense, and of visual and aural acuteness, which could be used by any intelligent, instructed man. These instruments, together with rules for examining and recording the tests, were put into the charge of instructed lay officials, who made the examinations and sent their reports to the surgical expert. If the latter found evidence of defect, a further opportunity for a more careful and full examination was given to the employee. If still found defective he was, if possible, placed in some other position, where his special defects could do no harm.

The ratio of those defective in color-vision among 2,000 examined was four per cent.; and that of those otherwise defective in vision or partially deaf was ten per cent. The Pennsylvania Railroad operates 5,000 miles of track, and employs about fifty thousand men, of whom about ten thousand are dependent upon color-signals for guidance. It may be easily seen, therefore, that it was no small task to attempt to eliminate the defective. Yet it has been successfully accomplished, and the general manager, Mr. Charles E. Pugh, writes in most positive commendation of the good results of the work.

Other railroads are now rapidly following the example of the Pennsylvania Company. They cannot, however, take away from it the great credit due to having so successfully applied a measure which cannot fail to be the means of saving lives and preventing injury.

INSTRUCTION OF TEACHERS IN THE FIRST SYMPTOMS OF TRANSMISSIBLE DISEASES.

The Health Department of Brussels recently prepared a pamphlet containing some brief instructions as to the first symptoms of transmissible diseases, for the use of teachers in the public schools. Through this means it was believed that infectious diseases could be more quickly recognized and isolated. The pamphlet of instructions has been translated by Dr. L. B. Tuckerman, published by the Cleveland Board of Education, and introduced into the public schools of that city. The plan is, in theory at least, a good one. Only experience will show whether it practically amounts to anything. It certainly should be part of a teacher's education to learn how to tell the grosser defects and more dangerous diseases from which their pupils may be suffering. The pamphlet of instructions is tolerably complete, but in form and composition might be improved.

American Public Health Association—Official Announcement of the Lomb Prize Essays.—Mr. Henry Lomb, of Rochester, N. Y., has offered through the American Public Health Association the sum of $2,800, to be awarded as first and second prizes for papers on the following subjects: 1. "Healthy Homes and Foods for the Working Classes"—first prize, $500; second prize, $200. 2. "The Sanitary Conditions and Necessities of School-Houses and School-Life"—first prize, $500; second prize, $200. 3. "Disinfection and Individual Prophylaxis against Infectious Diseases"—first prize, $500; second prize, $200. 4. "The Preventable Causes of Disease, Injury, and Death in American Manufactories and Workshops, and the Best Means and Appliances for Preventing and Avoiding them"—first prize, $500; second prize, $200. All essays written for the above prizes must be in the hands of the Secretary, Dr. Irving A. Watson, Concord, N. H., on or before October 15, 1885. The judges will announce the awards in the second week of December, 1885, at the annual meeting of the American Public Health Association. Competition is open to authors of any nationality, but all the papers must be in the English language. The American Public Health Association earnestly appeals to those able to compete to take part in this work, which it is believed will do much to augment the health, comfort, and happiness of the people.

News of the Week.

Reduced Rates to Albany.—The New York Central & Hudson River Railroad will sell excursion tickets to Albany at $3.10, good for thirty days, and available without special credentials as delegates or members of medical societies, except in case of an increase in rate *before* the date of the meeting at Albany (February 3d), when all delegates presenting their credentials will be supplied with excursion tickets at $3.10.

A Surgeon Inoculated while Operating.—The sad death of Dr. Atkinson, of Brooklyn, prompts Dr. John D. Mulhane, of Steubenville, O., to write us an unfortunate personal experience of his own. On March 10, 1884, Dr. Mulhane removed from the inferior carotid triangle of a woman a tumor of character unknown. During the operation and while holding the tumor, the needle point plunged into his middle finger, giving an opportunity for a pure inoculation of the tumor. Three days after a pustule appeared, and five days later the doctor had a temperature of 104° F., and was delirious. He put himself upon carbolic acid and took seven minims daily for five days. The glands in the axilla became swollen, the wrist-joint suppurated and had to be opened. In August Dr. M. had severe boils and carbuncles. At date of writing Dr. Mulhane states that the axillary glands are enlarged and a very suspicious eruption is appearing on his body. He fears that he was inoculated with a specific virus. We should say, however, that our correspondent is a little "over anxious," and has had only a septic infection.

Is there a Form-Blindness?—A daily paper quotes a prominent artist of this city as saying: "I have during many years of art teaching, and in various other ways, encountered a peculiar form of visual defect which is akin to color-blindness. Instead, however, of being insensible to a difference in color, these people appear to have lost, if indeed they have ever possessed, the power of perceiving clearly defined forms—form-blindness, in other words. I have sometimes placed objects in the shape of hexagons, or octagons, or decagons, or even so common a shape as a pentagon, or a five-pointed star before these pupils as a test, and almost invariably they were unable to distinguish one form from another, even when with careful distinction the differences were explained to them. This fact is a curious one, and I do not know whether it has ever been treated scientifically or not."

Color-sense depends upon the integrity of the retina, but the forms of objects are dependent, speaking generally, upon the integrity of the refractive media. The defects above referred to are very likely due to astigmatism. There is, however, a disease of the retina called micropsia, in which objects seem smaller than they really are. And there is another retinal disease, described by Förster and called metamorphopsia, in which horizontal lines look crooked and curved to the patient.

Congress and Cholera.—As we predicted, the House Committee on the Public Health has decided that by reason of the late stage of the season and the crowded condition of the calendars, it would be impossible to pass during this session such a bill to protect the public health as was recently prepared by the delegates from the various State Boards of Health assembled in convention at Washington. The Committee, however, decided to recommend the appropriation of $25,000 for the National Board of Health, and $500,000 to be used at the discretion of the President, in preventing the spread of cholera, should it appear in this country before the next Congress assembles.

Iron for the Blood.—*Mike* (something of an invalid)—The docther says Oi must dhrink oirun for me blood.

Mary—Shure, an' how can yez dhrink oirun, Moike?

Mike—By meltin' it, av coorse.

Mary—But yez can't dhrink hot melted oirun, ye fule.

Mike—Oi knaw Oi can't dhrink hot melted oirun, but it's meself that can wait till it cools.

Mortality in Tennessee Prisons.—The Legislature of Tennessee has ordered the appointment of a special committee to investigate the treatment of convicts in the main and branch penitentiaries, startling facts as to the death-rate having been reported to the State Board of Health by Dr. Sims, chairman of the Committee on Prisons. It is stated that during the past two years, out of a population of 1,323 convicts, 205 died. Over five hundred convicts are confined in the main prison.

The "Index Medicus" has suspended publication pending the question of its being issued in another shape. We sincerely trust that the able editors will find that they can continue their work by presenting it in a more available and practical manner.

A Munificent Bequest.—A legacy of $400,000 was recently left by Mrs. Philander Peck, of Chicago, for the erection and support of a Home for Incurables.

The Bill to Regulate the Practice of Medicine in New York was introduced into the Assembly on January 27th.

Medical Practice in the Argentine Republic.—Correspondents of the *South American Journal* give some glowing accounts of the prospects for medical practice in the Argentine Republic: "All the medical men here are said to be making fortunes, and there is still room for 'healthy competition.' The ordinary charge for a consultation at a medical man's house is said to be two dollars (about 8*s.*); for a visit, four dollars, say 16*s.*; for attendance at confinement when all goes well, about twenty pounds; but when any special care or operation is required, these fees mount up to hundreds of pounds. Accounts for medical attendance are sent in, and paid without remark, which would make the hair of a paterfamilias in the 'old country' stand on end. My friend mentions the following fees as having been lately obtained by doctors who, though of good standing, are not looked on as 'stars'; for extraction of ovarian tumor, £1,200; amputation of arm, principal, £600; amputation of arm, two assistants, each, £400; delivery with operation, £400; attendance during typhoid fever, £200; visit by a physician for dropsy, £50; consultation fees, £20 and upward." Expenses are high, however, and before one can practise medicine he must pass an examination before the Government Medical Board, and must be able to speak Spanish.

THE BILL TO REGULATE THE PRACTICE OF MEDICINE IN NEW JERSEY.—The provisions of this bill, which is or is to be before the New Jersey State Legislature, provides for a Board, to be appointed by the Governor, and to consist of nine members, who must be graduates of a medical college, and with not less than five years' practice in medicine or surgery. Seven members are to be chosen from a list submitted by the State Medical Society, and the other two from a list submitted by the Homœopathic State Medical Society. Two sets of questions will be prepared, each set respectively by the regular and homœopathic societies, and the examination will be in anatomy, physiology histology, pathology, principles, and practice of medicine, general chemistry, surgery, and obstetrics.

THE MASSACHUSETTS STATE MEDICAL EXAMINERS.—The Governor of Massachusetts in his annual message accuses the official medical examiners of, at times, charging fees for unnecessary autopsical examinations, and cites one case in which the examiner charged thirty dollars for making a formal autopsy on the body of a man killed instantly by a railroad accident in broad daylight. *The Boston Medical and Surgical Journal*, comes vigorously to the defence of the medical examiner system. The profession has certainly looked at Massachusetts as being much in advance of other States in this respect.

PRESCRIBING DOCTORS' WIVES.—A novel case is reported in *The Lancet* in which a widow lady of Glasgow sued a medical man to recover £50 for injuries to health produced by medicines prescribed and supplied in the absence of the medical man by his wife. It was sought to show that in this case the wife was the agent of her husband, and that he was responsible. The injuries alleged were salivation and its consequences, due to a quantity of mercury prescribed by the defendant's wife. The defendant denied that the powder given contained anything unusual either in quantity or quality, and, while admitting that his wife occasionally assisted "in the shop" in his absence or that of his assistant, denied that his wife had any authority to prescribe. This view was taken by the judge.

ST. MARY'S HOSPITAL, BROOKLYN, N. Y.—The second anniversary dinner of the staff of this Hospital was held on Monday evening last, and was a very enjoyable affair. The medical board, the chief of which is Dr. John Byrne, is composed of specialists in different branches, each having continuous service. So far the staff is perfectly satisfied with the working of the plan, and took occasion to felicitate itself accordingly. A number of distinguished medical men from Brooklyn and New York were present, and cordially responded to the toasts.

THE ALBANY BASIN.—The dock front of Albany, N. Y., is a curve concave toward the city. Across the chord of this arc is built a pier, about four thousand feet long, parallel with the current of the river, leaving between it and the dock front proper a basin four thousand feet long and from one hundred and fifty to four hundred and fifty feet wide, containing some thirty acres. Into the northern end of this basin opens the Erie Canal. This basin was intended as a harbor for canal boats, and it was expected to maintain in it seven feet of water at low tide. The basin has, however, become filled with mineral and organic matter from two sources, so that now at low tide from five to six acres of the bottom are laid bare. The New York State Board of Health has sent in a report declaring the basin a nuisance and a source of danger to the citizens of Albany.

Reviews and Notices.

THE AMERICAN HOMŒOPATHIC DISPENSATORY. By THEODORE D. WILLIAMS, M.D. 8vo, pp. 698. Chicago: Gross & Delbridge. 1884.

IN some respects the work is a very satisfactory one. Its general directions for the preparations of drugs, and the utensils, weights, and measures necessary for dispensing them are clear and to the point. This may be owing to the fact that the greater portion consists of quotations from King and the United States Dispensatory. The chapter on General Formulary is also gratifying, consisting as it does of directions for preparing various articles of diet for the sick, and containing a selection of recipes selected from "old-school" works. To meet in a homœopathic dispensatory with the prescription for Plummer's pills, for acute rheumatism a mixture of salicylic acid and bicarbonate of soda, etc., is a hopeful indication of the tendency of progressive homœopathy. The appendix, giving the ingredients of the principal natural mineral waters, will also be found useful. In short, in those parts of the book in which the author has had to do nothing but copy from standard medical works he has accomplished his task with considerable judgment and produced a compilation of some value.

As much, however, can hardly be said for the greater portion of this literary effort—the six hundred and fifty pages devoted to special homœopathic pharmacy. In the preface we are told that the *raison d'être* of this book was a presumed want of the homœopathic practitioner, "in view of the fact that the American Institute of Homœopathy, who are the only proper persons to arrange and authorize a National or standard pharmacopœia, had abandoned the publication of such a work." If this work really represents a homœopathic dispensatory we think the American Institute of Homœopathy did themselves credit in abandoning its publication; for we have no hesitation in saying that six hundred pages of drearier or more puerile repetition it has never been our lot to meet with. It is an insult to the intelligence of every homœopathic physician in the United States to be told four times on every page that one and nine are ten, and ninety-nine and one make one hundred. This is no exaggeration or parody, but gives exactly the contents of this part of the book. Under each article of the materia medica are given the synonyms, vulgar names, and chemical formula; then the preparations and how to make them. This latter information comprises the great bulk of the work and informs the reader that "to prepare the *first decimal* trituration it requires to *nine parts* of milk-sugar *one part* of the unoxidized sulphate. Deposit the sulphate in a porcelain mortar, and add *three parts* of milk sugar, and steadly triturate for ten minutes; add *three parts* more of milk-sugar and again triturate for ten minutes; then add balance of milk-sugar and triturate for twenty-five minutes." This appears *verbatim et literatim* under every article, with such slight alterations as the substitution of "tincture" for "trituration," or "ten" for "twenty-five" minutes. We know that the author does the average homœopathic practitioner gross injustice; that the latter does not require to be officially informed that four and six make ten, or that ninety-nine and one are a hundred. Nor does he require the didactic wisdom of Dr. Williams to explain to him that "a solvent is a fluid substance in which various solid substances do not possess the property of resisting solution."

HANDBOOK OF THE DIAGNOSIS AND TREATMENT OF SKIN DISEASES. By ARTHUR VAN HARLINGEN, M.D. With two colored plates, pp. 282. Philadelphia: P. Blakiston, Son & Co. 1884.

Of writing books on skin diseases there seems to be no end. Nevertheless we must accord some praise for the present volume. It is intelligently written, and the author shows a proper appreciation for the wants of the general practitioner. Pathogenesis and pathological anatomy are for the most part omitted, and the work is devoted to diagnosis, symptoms, and treatment. The subjects are arranged in alphabetical order in the manner of Fox's "Epitome."

ON THE USE AND ABUSE OF PESSARIES. By GEORGE G. BANTOCK, M.D., F.R.C.S., Edinburgh. Second Edition. London: H. K. Lewis. 1884.

Dr. BANTOCK's views on the use of pessaries, as well as their frequent abuse, are already well known to the profession of England and America. The second edition of his original pamphlet is considerably amplified and, as he states, has been entirely rewritten. He treats the subject of pessaries from a practical point of view, which will do much to popularize his teachings with the general practitioner.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 26, 1885.

DANIEL LEWIS, M.D., PRESIDENT, IN THE CHAIR.

AFFECTIONS OF THE EAR INFLUENCED BY, OR DEPENDENT ON, MALARIA AND DEFECTIVE DRAINAGE.

Dr. O. D. POMEROY read a paper on the above subject (see p. 113).

Dr. HACKLEY could recall only two cases in which acute aural disease occurred in patients suffering from malaria, and in these it was while the patients were taking small doses of quinine. The occurrence of aural affections due to malarial poisoning would probably depend upon the absence of several distinct conditions, such as pharyngeal diseases, mentioned by the author of the paper, vaso-motor disturbances, etc.

So far as his experience went, the admixture of malaria, aural disease, and other well-defined influences has been so pronounced that he had been unable to decide which was primary.

Dr. BARUCH regarded cases of malarial ear-disease as extremely problematical. He believed that, in all the cases of this kind which had been reported, there existed an error in diagnosis. That quinine was beneficial in diseases other than malarial was well known, and he hoped that more distinct observations would be made before endorsing the view that ear affections may enter the class of malarial diseases. Dr. Baruch discussed at some length the effects produced by malaria, presented statistics to show that malarial fever did not occur in the city of New York nearly so frequently as appeared from the death-certificates sent to the Board of Health, and also commented on the reported cases cited by the author of the paper, with criticisms referring especially to errors in diagnosis.

Dr. J. C. PETERS said a word in defence of malaria, and believed that it prevailed in the city of New York to a much greater extent than Dr. Baruch would have us believe, for the reason that the drainage for the natural water-courses was extremely deficient; in many places no provision at all had been made for it, and consequently the subsoil of a very large portion of the city was constantly damp, at times saturated, and also thoroughly impregnated with sewer-gas and other noxious substances. He cited several cases in which the symptoms of malarial disease were unmistakable. He believed that pure malarial fever in the city of New York was very common, and that malarial poisoning mixed with other malignant influences was exceedingly frequent.

Dr. CRANMER referred to the case of General Garibaldi, under his care in 1859. The patient complained of excessive pain in his left ear, for which the doctor used fomentations of hot water and laudanum, but complete deafness developed within a few hours. The General then took, of his own accord, thirty grains, probably, of quinine, and on the following morning was entirely well again. Dr. Cranmer also referred to deafness occurring in the later stages of phthisis, and asked concerning its cause in those cases.

Dr. GARRISH thought it important to search for the cause of ear troubles, such as impacted wax, scarlet fever, etc., before attributing the affection, in any given case, to malaria. He had seen cases in which deafness had been produced by quinine, but had not seen disease of the ear produced by malaria.

Dr. HOLCOMBE, during a practice of thirty-five years' standing, had not seen a case of ear-disease which could be distinctly attributed to malaria. Undoubtedly it was correct to say that diseases of the ear were influenced by malaria, and for those who regarded malaria as a cause of ear-disease, some of these cases would be put down as due to malaria. He was sorry that malaria should be looked upon as the source of one more evil, and was glad to hear that Dr. Pomeroy did not subscribe to the German view concerning malarial diseases of the ear. The cause of the ear-disease should be diligently searched for, such as typhoid, measles, scarlet fever, syphilis, tuberculosis, diphtheria, etc., and he believed that it could be found independent of malaria, although, undoubtedly, the course of the disease in patients living in malarious districts, constantly exposed, was influenced by the poison.

Dr. POMEROY, in closing the discussion, said that he did not subscribe to the view of the German observers who held that there was something peculiar in ear affections dependent upon malaria, as there was nothing peculiar about the ear-disease in cases which had been placed in this class. Deficient house-drainage, with imperfect soil-drainage, meant dampness, which favored relapses of catarrhal affections, and under such circumstances the development of ear-disease was especially favored. Malaria, however, he believed, was not to be regarded as the primary cause, acting at the inception of acute aural disease, although inflammatory and also painful affections of the ear were likely to be aggravated, possibly excited, by the influence of malaria and sewer-gas.

Dr. A. HADDEN, from the Committee on Hygiene, then read a report on

THE MANURE NUISANCE.

From the evidence of Drs. Chandler, Doremus, and Draper, decomposition of such material gave rise to gases which were unhealthy to respire. As to the production of specific disease by such exhalations, the Committee did not express an opinion, but simply spoke of the general insalubrity of the atmosphere in the immediate neighborhood of decomposing heaps.

The conclusion reached by the Committee was that the manure-dumps of this city were nuisances and detrimental to the public health, and that all reasonable means should be used to do away with them entirely. The Committee recommended that the Society insist upon the health officers of the city lessening the nuisance by some feasible method, such as pressing and baling the manure, which had already been done successfully in a number of large stables, or by some other method equally efficient. The report was accepted.

After the transaction of routine business the Society adjourned.

CLINICAL SOCIETY OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Meeting of January 3, 1885.

C. L. Dana, M.D., in the Chair.

A discussion on

INTRACRANIAL HEMORRHAGE IN CHILDREN

was opened by Dr. S. J. McNutt, who first presented the following cases :

Case I.—A boy, four years of age, was well until a year ago, when he had an attack of fever, which was accompanied on the third day with convulsions, lasting twenty-four hours, after which he remained unconscious for a week, having to be fed by force. For six weeks he did not speak, and had to be taught again as though just learning. On return of consciousness it was noticed that he was paralyzed on the right side, and that the angle of the mouth on the same side drooped. He first came under notice on July 2d, with still some drooping of the mouth and the tongue drawn to the right. These symptoms are not now present. He could walk, but had not as much strength in the right as in the left leg, and the toes were curled under. The fingers were flexed, and there was strong pronation of the right arm. All the muscles responded to faradism, but the extensors of the wrist and those of the anterior tibial group very imperfectly. The extremities of the affected side were smaller and shorter than those of the left.

Case II.—Had a specific history. An attack of indigestion at the age of ten months was followed by convulsions of the left side, which resulted in contraction of that side and a drooping of the corresponding angle of the mouth. Although this child was sixteen months old, it had not yet walked, and though free from contractions, there was a disinclination to use the left hand. The angle of the mouth on the same side was more readily tired, and sometimes drooped.

Case III.—Had an attack of fever at the age of nine months which lasted for several days, and when it abated left the child dull and sleepy. After this it had daily convulsions, never walked or stood alone, and died fourteen months later of diphtheria.

Case IV.—A girl seven years of age, had an attack of small-pox, which was followed by contractions of the fingers of the right hand and dragging of the toes of the corresponding foot. The first symptoms of cerebral trouble were noticed ten days after the eruption, when she was seized with convulsions, and was soon unconscious. While in this condition the mouth was drawn to the left side and there was internal strabismus of the right eye, but both were corrected in a few weeks. She had to be taught to speak again. At the end of four months she began to walk, although the contractions still persisted, and there was some atrophy of the paralyzed side.

Case V.—A child, nine years of age, had paralysis of the right arm and head, which followed convulsions at two months. The thumb was flexed into the palm, and the forearm upon the arm. This limb was shorter than that of the other side.

Dr. M. Allen Starr kindly allowed the mention of

Case VI.—A boy, ten years of age, never had walked, and at the age of six months could not hold up its head. He was born after a long and difficult labor, instruments being resorted to—the marks remaining for a long time. He had convulsions for ten days after birth, which were more severe on the left than on the right side, and internal strabismus in the left eye, which still existed at times. The hands were held semiflexed and pronated, and the forearms flexed upon the arms, but all these contractions, except those in the little fingers, were easily overcome. The thighs were adducted, and there were contractions of the tendo-Achilles and under each knee. The toes were curled under, and during the last few months talipes varus had developed in the left foot. His intelligence had improved lately and his memory was uncommonly good. He laughed, sang, and for two years had been able to talk in monosyllables. When laughing, the mouth was drawn to the right side. Sensation was normal.

In all these cases save one there was paralysis of both extremities upon one or both sides of the body. The simultaneous paralysis of an arm and leg on the same side pointed, as a rule, to a cerebral cause. In addition there was one case with aphasia and right hemiplegia, lasting six weeks, facial paralysis, and deviation of the tongue to the right side ; in another there was left hemiplegia, and drooping of the angle of the mouth ; one with double hemiplegia never spoke after the seizure, while still another, with right hemiplegia, had the mouth drawn to the left side, internal strabismus of the right eye, and aphasia lasting six weeks ; in the other case, where only an arm was paralyzed, it became contracted and shortened, a condition which was characteristic of the other cases.

In locating the lesion of intracranial hemorrhage we were guided by a number of facts. Aphasia was particularly noted in the two hemiplegics, and when facial paralysis occurred it was on the same side as the affected limbs, which proved the lesion to be above the pons.

PATHOLOGY.

Thirty-four autopsies, details of which had been collected by the speaker, furnished the following : A right hemiplegic presented upon the surface of the left hemisphere a depression which communicated with the ventricle of that side ; a case of double hemiplegia with idiocy had atrophy of the cortex about the lower two-thirds of the fissure of Rolando, on both sides ; one of right hemiplegia had atrophy of the whole left hemisphere ; another, with right hemiplegia, had the middle upper part of the left hemisphere occupied by a cyst, about which hæmatoidin crystals were formed ; and one with left hemiplegia and strabismus had atrophy of the right hemisphere, particularly in the region of the fissure of Rolando. The lesion, then, which had generally accompanied infantile hemiplegia, had been either shrinking of the whole of the opposite hemisphere, or a depression in the surface about the fissure of Rolando, into which the gray matter of the cortex dipped. Where the sutures were not ossified asymmetry of the skull resulted, but if ossification were complete previous to its occurrence a serosity filled the vacuum. Sections of the pyramidal tracts colored deeply with carmine, as though a secondary degeneration had occurred. Rilliet and Barthez mentioned the transmission of the degeneration to the acoustic and optic nerves in some cases. Hérault advanced the opinion that this staining might be due to the predominance of the neuroglia from arrested development, rather than to new growths. He found similar staining in all children under four years of age.

The lesion was supposed to proceed from an encephalitis or clot, and to travel from the convexity. West gave a number of autopsies following these seizures in which hemorrhage was present. The theory of a clot was favored by the large number of cases that, presenting by the breech or feet, received an injury which apparently induced the hemorrhage. In a case which the speaker had reported there was a foot presentation, a difficult labor, and instrumental delivery, followed by convulsions, complete paralysis, and nasal regurgitation of food The autopsy revealed an atrophy about the fissure of Rolando upon both sides. Over

FIFTY CASES OF SPASTIC RIGIDITY,

where a difficult labor was the supposed cause, were reported by Little. In one of them atrophy of the opposite hemisphere with evidence of an old clot was found. In a number of cases collected by the speaker, particularly three of breech presentation, followed by convulsions, paralysis, or rigidity similar to that of the initial stages of the disease, and where death occurred within one,

two, or three weeks, the autopsies showed a fresh clot, which furnished still more conclusive evidence. In favor of this hemorrhagic lesion we had the fact that intracranial hemorrhages in children were as a rule meningeal. Eustace Smith said that under three years it was rare to meet with any other form. The production of the symptoms may be thus accounted for, as meningeal hemorrhages often occurred simultaneously on both sides.

ETIOLOGY.

The predisposing cause seemed, in one of the doctor's cases, to be a specific taint; weakness is also considered to be an etiological factor. A number of Rupprecht's cases were premature, and probably a congenital weakness of tissue was present. In some cases the seizure followed a febrile attack. Stiner suggested that fatty degeneration of the walls of the vessels occurred from the pyrexia. The disease had followed measles more frequently than any other disease, and it had been suggested that a profound alteration of the blood might be an element in its cause. The hemorrhage at birth which induced this condition seemed to be connected with the after-coming head, when it usually occurred at the convexity, while in vertex cases it was more common about the cerebellum and at the base of the brain, destroying life more rapidly. Six vertex cases—living fifty-five, thirty, forty-eight, forty-eight, one hundred, and one hundred hours respectively—showed, at the autopsies, effusions about the base of the brain, in the cerebellum, or limited to the posterior cerebral lobes, but in none of the breech cases were these portions involved. According to text-books the hemorrhage was always at the base of the brain or involved only the posterior cerebral lobes. The fact that the hemorrhage at the convexity had not been recognized was probably due to the longer period of life in those cases.

DIAGNOSIS.

The diagnosis of the one-sided variety was not difficult, for the paralysis with apparent shortening, dating from childhood, following convulsions and contractions, presented a picture which, as Rupprecht said, "once seen could never afterward be mistaken." The double hemiplegia offered more difficulties, as it had to be differentiated from a number of other morbid conditions.

THE PROGNOSIS

was not hopeless, although until a very late day the favorite method of treatment had been to allow the patient to outgrow the disease. Rilliet and Barthez considered that when improvement took place it was due to the fact that other portions of the brain took on the functions of the affected part, and a number of the cases mentioned in this paper improved while under observation.

TREATMENT.

In treating the contractions use might be made of passive exercise, central galvanization, faradization of the opposing muscles, cold douches, splints and other orthopedic apparatus, etc.

Dr. Charles Henry Brown presented two other patients illustrating the same disease:

Case I.—Boy, aged two years and seven months, whom he had been treating for seven months. The presentation was transverse and the labor long and difficult, the child being delivered by podalic version. When one month old its left arm was powerless, and at six months the leg of that side was in a like condition. Contractions then began in the arm. At fourteen months its sight and hearing became affected on this side. He did not speak until two years old, and then only a few words. The development of the affected side was fair, though at first there was atrophy. The flexor muscles were contracted, the thumb and fingers into the palm; the leg was thinner than its fellow, and when standing the heel could not touch the ground. Tendo reflex on this side exaggerated. He had epileptic attacks, was excitable and ungovernable. The treatment had been the application of the combined currents, from three to four times weekly, to the extensors of the upper and lower extremities, making each muscle respond well at every sitting. The reactions were normal. The improvement in the arm was remarkable, but the leg and foot had not done so well although they could be used.

Case II.—Girl, aged seven years, with double hemiplegia, was born by the breech, and the labor was prolonged and difficult. The late Dr. Hart thought the child dead, but his efforts at resuscitation were rewarded at the end of half an hour by seeing it begin to breathe. It did not cry for eight hours, but then did so incessantly. During the first two years it suffered from insomnia, only falling into a doze, from which the slightest noise would waken it. After birth all its muscles were relaxed, and continued so for two years. Contractions began early and grew worse rapidly, so that in a few months the hands, especially that of the right side, could not be opened. When first seen, about a month ago, she was tall, well developed, weighed about forty pounds and had a large head, the face presenting rather an idiotic expression, owing to the drooping of the chin and constant dribbling of the saliva; utterances were thick and hard to understand. In spite of this idiotic appearance she was bright, was a willing scholar, and read quite well. The hands and arms were flexed and adducted, the right more than the left. She could not stand, but when supported there was contraction of the adductors and flexors. The knees interfered and the feet interlocked, while the heel did not touch the ground. Choreic movements, when sitting, were noted, and when excited athetoid movements of the extremities. Sensation was good but no tendo-reflex could be elicited. She was emotional, easily unstrung, and sometimes cried for a long time. The right side was atrophied and gave a more feeble response to faradism than the left. She was unusually healthy, and slept well, with complete relaxation of all contractions and cessation of the choreic movements. Special senses were normal. A left antero-lateral curvature of the spinal column existed, for which she had worn a spinal jacket.

THE TREATMENT

had consisted in applying the combined currents, under which the improvement had been very decided. The dribbling of the saliva had decreased, and the mouth could be kept closed, both cheeks and hands moved better, and she could place her heel to the ground, and raise her head and arms. The choreic movements were less, and she had better control of the muscles generally.

THE POINTS OF INTEREST IN THESE CASES

were, first, the fact of their dating from birth and following difficult and prolonged labors, where the delivery was by the feet, which pointed strongly to meningeal hemorrhage as a cause of the difficulty; second, the late effects, contractions, etc., and the comparatively bright mental capacity of both children; third, the decided and satisfactory improvement in both under electrical treatment, and the encouragement it held out to us in similar cases.

Dr. Græme M. Hammond presented the following history: A boy, three years of age, had been perfectly well up to last summer. In June he fell down stairs, but apparently received no injury save a few bruises. A month later he fell backward from a chair, striking upon the head, and also during this month had an attack of cholera infantum. In August had a fit which lasted an hour, followed by three weeks of repeated spasms. The mouth, tongue, trunk muscles, and left arm were subject to convulsive movements for two weeks. The left eye was pulled to the extreme left, and the left testicle was much swollen. He held his urine and fæces well. The left arm and leg were paralyzed for five weeks, when he

became unable to stand, both limbs being too weak to support the weight of the body. There was complete loss of vision and inability to swallow for a time. Suffered from insomnia for three months, and when he did sleep it was only by burying the head in the pillow and resting upon the vertex, with the knees drawn up. There was no rigidity or retraction in the cervical region. The child is now apparently idiotic, deaf, acts as though in pain, and has from four to five epileptic attacks in the day and night. There is considerable loss of muscular power on the left side.

In this case there was without doubt a hemorrhage upon the surface of the brain, involving gradually the motor centres, first of the trunk and legs, and then progressively passing downward to the centres for the face.

Dr. S. M. Roberts related the history of several cases.

Case I.—Some years ago he had had an opportunity of making an autopsy upon a patient, a child, who, suffering from an attack of croupous pneumonia, suddenly died. He found a large clot covering the surface of the left hemisphere, which dissected up the pia mater and caused some laceration of brain tissue.

Case II.—Another, a boy, that he had seen at the age of three years, had had, the year before, convulsions lasting twelve hours, and followed by stupor. He was immediately afterward paralyzed on the left side. The use of the limbs was recovered, and he continued to improve for five or six months. He had talipes and slight contractions, but no wasting in the paralyzed parts. When three years of age he was suddenly convulsed and died, but no autopsy was allowed. In this case the hemiplegia was probably due to a cerebral clot.

Case III.—In another case, also a boy, seven years old, there was an attack of scarlet fever at two years, accompanied with very marked swelling of the glands. Five weeks after the subsidence of the fever he was noticed to be again feverish, and suddenly his whole body became stiff, and the right arm and leg "worked," the left angle of the mouth was elevated, and the face was pale. The next day there was no motion in the limbs, but consciousness had returned, and within a few weeks the mouth straightened and the limbs could be used. At the end of three months, recovery seemed complete, but the muscles on the paralyzed side were still weak. Four or five years after the first attack the child had petit-mal, did not fall but became frightened, the eyes stared, and the whole body trembled. He continued to have these attacks for five months, having from four to thirty fits in twenty-four hours. They were checked by the bromide of potassium.

The paralysis in this case was probably

A TYPICAL HEMIPLEGIA FOLLOWED BY CORTICAL EPILEPSY.

The patient recovered from the paralysis more perfectly than usual.

Case IV.—Another case, that of a girl, was said at eight months to have had measles and scarlet fever—the first being complicated with bronchitis. The child was convalescing nicely, but was found one morning paralyzed upon the right side. After this seizure she could make her wants known, played about and seemed quite well. The paralyzed side was anæsthetic. The paralysis in the leg improved a few weeks after the attack, but the grasping power in the hand was never regained. The face recovered entirely, but though she could be understood her speech always remained thick. The interesting feature in this case was that after the attack she had no rise in temperature, played and crept, dragging the paralyzed limb after her. She subsequently died of congenital heart defect, with symptoms pointing to cerebral hemorrhage. In the heart was found stenosis of the pulmonary artery, so that a lead pencil could hardly be passed in, and an opening in the septum between the ventricles. An

EMBOLUS

seemed probable in this case. In a case of phlebitis of the lower extremity ("Trans. of the London Path. Soc."), death was caused by an embolus in the brain, which gave rise to the query, How did it pass through the lungs? This was answered at the autopsy, however, by the discovery of a perforate foramen ovale through which the clot had passed.

Dr. C. A. von Ramdohr thought that where injuries to the fetal bones occurred during delivery it was due to either a contracted pelvis or to the application of the forceps above the superior strait before the head had had time to be properly moulded. If the forceps had to be applied it should not be until moulding had taken place, should be late rather than early, and the delivery should be performed as rapidly as possible.

The Chairman, referring to the etiology of intracranial hemorrhage in children, recalled a case of

MENINGEAL HEMORRHAGE FROM CONGENITAL PURPURA HEMORRHAGICA.

An infant, female, born at term after a long and difficult labor, requiring the use of the forceps, with vertex presentation, showed on the second day evidences of purpura, viz., hemorrhagic spots on the limbs, trunk, and head, bleeding from the vagina and bowels. The child was weak, anæmic, and suffered from frequent tetanic spasms. On the fourth day it developed a right hemiplegia, and next day died. No post-mortem. In speaking of prognosis he also related a case of a boy, now fourteen years old, who, at the age of four, had an attack of right hemiplegia, following convulsions. The attack was gradually recovered from, but whereas he was right-handed previous to the seizure, he was now left-handed, having accustomed himself to its use while still paralyzed. He was quite well and bright until the age of ten, when he received a severe fall, and became subsequently dull and epileptic.

Dr. McNutt presented a

LARYNX REMOVED FROM AN INFANTILE HEMIPLEGIC

who had had stridulous breathing with dyspnœa. It was of small size and showed a number of small growths composed of natural tissue, and supposed to be caused by the puckering of the mucous membrane from the arrested development. Little was the only author who made mention of this complication, and then only incidentally.

Dr. M. J. Roberts made some

REMARKS CONCERNING TREATMENT.

The main therapeutic indications, from the mechanical standpoint, were to sustain the patient in natural positions and to artificially direct (co-ordinate) his movements so as to encourage physiological activity. For a patient who was able to move all parts of the body, but unable to sit up or hold the head erect, or to co-ordinate any of his movements, Dr. Roberts had devised an apparatus which effectually supported the spine, maintained the head erect, overcame the flexions of the upper and lower extremities and directed their movements in normal paths. The apparatus was exceedingly light, not irksome to wear, did not interfere with the normal movements of the body, or excoriate the soft parts, was easily removed and reapplied, and possessed the merit of being inconspicuous. Dr. Roberts made brief comments on four patients suffering from infantile hemiplegia, photographs of whom he exhibited. Numerous photographs illustrating mechanical appliances devised by him for these patients were also shown, together with several novel instruments and appliances of general and special applicability.

Dr. William H. Porter presented a specimen showing a lesion of the lung which was probably due to syphilis, and which might be classed as a

SYPHILITIC INTERSTITIAL PNEUMONIA,

pulmonary syphilis of adults, or syphilitic phthisis. The lung showed cheesy nodules, large and small cavities, and was introduced on account of its bearing upon the approaching discussion upon phthisis.

The history of the case was given in full.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DEATH OF DR. HERBERT DAVIES—SIR ANDREW CLARK AND THE TEMPERANCE QUESTION—DR. LAUDER BRUNTON ON GOOD FEEDING.

LONDON, January 1, 1885.

By the death of Dr. Herbert Davies the profession has lost one of its most honorable and upright members. His father, Dr. Thomas Davies, was physician to the London Hospital and introduced the stethoscope into British practice, having learned its use in Paris under Laennec himself. Dr. Herbert Davies succeeded to his father's practice in Finsbury, and like him became physician to the London Hospital, then, as now, the great East End hospital. Having the good fortune to obtain the assistant-physiciancy at an early age, he became full physician at a much younger age than is common, and, having served his twenty years as full physician, became consulting physician. During his tenure of office he lectured on materia medica and medicine successively. Former pupils well remember his annual clinical course on auscultation, carried on at a time when clinical instruction was far from being as full and complete as it now is. Dr. Davies took great pains over this annual course and brought to it much practical knowledge acquired in the Vienna school, which is also embodied in his work on the lungs and heart. He was educated at Cambridge where he became a fellow of his college, and his medical education was received at the London Hospital, and he also spent a considerable time in study on the continent. This was of course much less common then (1848) than now. Your readers will remember him as the originator of the plan of treating acute rheumatism by free blistering. He also worked out the law regulating the relative magnitudes of the areas of the four valvular orifices of the heart. His paper on this subject was first published in the "Proceedings of the Royal Society," and the law is frequently called after him "Davies' Law." He enjoyed the absolute confidence of his professional brethren and consequently the largest practice at the East End of London as a pure physician. As a distinguished Cambridge graduate, he was made a Fellow of the London College of Physicians very early in life, filled most of the offices in the College, and would no doubt have been president, but for that modesty which always led him to put others before himself. Kindly and gentle in manner, always overflowing with humor, his presence in the sick room was always welcome, and thousands will regret the cheerful countenance and encouraging words which never failed to inspire hope or elicit a smile.

The temperance journals are rather wroth with Sir Andrew Clark because, in a recent address before the Young Men's Christian Association, he partially unsaid some of his former statements. In his recent utterances, although as before decrying the use of alcohol by healthy persons, he said there were some people not in robust health who were enabled to get through their work more easily by the use of alcohol "in physiological quantities." Sir Andrew is now accused of contradicting his former utterances. As he is such a ready orator and never uses notes, some inconsistency may easily occur between speeches delivered at different times and under different circumstances. Moreover, Sir Andrew Clark does not profess to be a personal abstainer and temperance advocate like Dr. Richardson. In combating the evil of drink the teetotallers should be glad of the assistance of any one who will help them to "put the brake on."

Dr. Lauder Brunton's Lettsonian Lectures on "Disorders of Digestion" are likely to prove more amusing than instructive, if we are to judge by the first of the course. Dr. Brunton is so learned—and, let me whisper it, sometimes dry—a writer that it is somewhat surprising for him to come out in a new character. Christmas festivities have doubtless warmed his heart. He naïvely confessed that he had been partaking of the hospitality of a city company, and proceeded to sing a pæan in praise of modern dinners, the order of the courses adopted in which was, he said, "thoroughly physiological"—*i. e.*, soup and bread, fish, chicken, meat and vegetables, bread and cheese, dessert. A simple dinner is surely not one of six courses. Physiological teaching points to plainer living and will also be slow to endorse Dr. Brunton in the meed of praise awarded by him to alcohol in speaking of its use as an adjuvant to digestion. It is rather at variance with modern notions about the "physiological quantity" to hear of "the value of the preprandial sherry and bitters, of the sherry with soup, of the champagne with its effervescing carbonic acid, and of the small glass of liqueur or brandy, and the like!"

MEDICAL MATTERS IN NORTH CHINA.

(From an Occasional Correspondent.)

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: While reading my latest MEDICAL RECORD which, by the way, is nearly three months old, I am tempted to write you a few lines while I am waiting here at this old Chinese inn for my muleteer to feed his animals.

This is a little wayside village inn, just two hundred and forty li (or eighty miles) from Chefoo, the nearest point of civilization, and at which I am stopping for dinner while on my way westward to Wei Hien, about one hundred and twenty miles farther, to which place I go to open a hospital and dispensary under the P. B. F. M. I am travelling at the express rate of three miles per hour; think of that in comparison to the speed of the big-wheeled engine which draws the express to Philadelphia. My conveyance is the Shentze, a sort of litter between mules, with a matting cover for protection from the sun, which here has a peculiar effect upon the brain, often producing very serious complications, that is, to foreigners; the natives very generally go bare-headed, experiencing no evil effects whatever. This conveyance of mine, though very jolty, having the combination of a pepper-box and sieve motion, nevertheless is not a bad institution, protecting one from the elements and at the sane time allowing a variety of positions, even to that of lying down and taking a good snooze if so disposed.

So far I have been three days and a-half on the road, including Sunday, which I spent with some friends in a large city about twenty miles back, and from which I resumed my journey this morning. This large city I speak of, Hwang Hien, is in the centre of a rich and populous district, and besides being a very old city, dating perhaps a thousand years back, it is a very busy place, transacting an immense amount of business in raw silks, which it sends to the south to be woven; furs, leather, blacksmith's materials, some rhubarb, and many other articles. The city has about one hundred thousand inhabitants, is surrounded by two massive walls, the outer brick and the inner stone; over each gate is a watch tower, and on the parapeted walls places for cannon in time of war. However, there are no signs of belligerents about, and everything looks peaceful enough, unless it be the clumsily moulded old cannon lying near the gates, partially covered with dirt, which have no appearance of ever having been used. The houses are substantially built of stone and half-burned brick, and are some of them quite elegant, though but one story high. A two-story house is never built, for fear of the "Fung Swey" or "wind and water" spirits, which are always flying in straight lines in the air, and which are apt to knock their heads against anything too high! But as I would like to introduce you to my friend Dr. Le, who has a medicine-shop near the inn, I will cut short my description and take you there. Passing out the inn door, by a number of very dirty looking street

restaurants, bumping against carts loaded with goods from Western China, with their mule teams tandem, stepping aside from the huge wheelbarrows, heavily loaded, with a man pushing with all his might, at the same time yelling lustily to the little donkey hitched by a long rope to the front of it, and then, in spite of all our care, getting punched in the ribs or back by the poles of a shentze, or mule litter, the muleteer expecting each man to look out for himself, we soon arrive at Dr. Le's shop, which has glass doors, and is gotten up regardless in the Chinese eyes. Dr. Le, a fat, good-natured old fellow invites us to sit down very politely, asks how our family are from our grandfather down, offering us, perhaps, his own pipe for a smoke.

While the palaver is going on we take a look around and are surprised to see a number of foreign bottles, and still more suprised to find them filled with foreign medicine. Upon inquiry we find that Dr. Le is a Christian and studied under Dr. Brown of Chefoo, and is now settled here, using entirely foreign medicine, and is making more than a comfortable living, in fact, is making money in Chinese estimation. Chief of all he uses santonine, for nearly every Chinaman has lumbricoids in great number, besides he uses nearly all the commoner medicines, such as castor oil, all the forms of potash, cathartics, iron, mercury, etc., and though he does not use them with all the philosophy and precision that we do, nevertheless he does very well for the light knowledge that he has.

He does something in the surgical line, too, and takes great delight in showing us his minor operating case; then, too, he has a fine case of catheters, a hypodermic syringe, and last, but not least, two stomach-pumps, which show signs of having been very often used. In truth, the common way of committing suicide here is by eating a large dose of opium, and many a man has he pumped out. Not long ago a grateful father gave him a hundred taels for saving his son, which is about one hundred and thirty-three dollars. Men of this kind are doing a great deal to establish foreign medicine in this country upon a firm basis, and in this man's case, though his knowledge of medicine is very limited, yet he is creating far and wide a sentiment of respect for the medicine of the "foreign devils," as they call us, and though I am a "medical missionary," using my influence for the propagation of the gospel, I yet feel it is also my duty to work in the interest of our noble profession, in which is my heart, and to give this people all that I can both of medicine and surgery, in both of which their ignorance is dark as night. For instance, imagine a man bleeding to death from a small wound, through ignorance of knowing how to take up an artery; or a soldier, badly wounded, allowing a leg to drop off and the dry, dead bone protrude, because no one could or would dare to perform a simple amputation; or a man, or hundreds of them for that matter, suffer agony with a belly full of worms, because the right man did not come along and give him a dose of santonine. But I am afraid I have already trespassed upon your space by my gossipy letter. I hope some time in the future, if acceptable, to write you of the prevailing diseases here, Chinese medicine, methods of treatment, of which not a few are worth attention; besides I myself meet a number of cases which are both unique and interesting, and might interest your numerous readers who are so widely scattered over the face of the earth.

HORACE R. SMITH, A.M., M.D.

HWANG SAN KWAN, NORTH CHINA, October, 1884.

THE NEW YORK ORTHOPÆDIC SOCIETY.—This Society held its first meeting on Thursday evening, January 29th, at which a paper was read by Dr. A. B. Judson, on the "Management of the Abscesses of Hip Disease." This organization, consisting of all the active workers in the specialty, has bright promises for future usefulness. There is no doubt that it will be plentifully supplied with material.

CLINICAL NOTES ON INTESTINAL CATARRH AND DYSENTERY.

(From our Mexican Correspondent.)

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In Mexico and in all southern countries the transition from the cool temperature of winter to that of the hot summer is very rapid. Thus in the months of March and April we have in Texas and here sometimes hot days, which seem to be even more oppressive than those of midsummer. This sudden change produces in all persons, more or less, a disparity between the income and expenses of the body. The glands of the central part of the body secrete less and their secretions are less liquid, the mucus of the stomach and intestines becomes more concentrated and viscid. Since perspiration is necessary to maintain the normal temperature of the body, by means of the rapid evaporation of the surface, the lymphatics of the intestines are constantly working with all possible energy to carry the liquids contained within that tube to the blood, to be transferred to the integument. The epidermis by this means being macerated all the time, becomes softer and more disposed toward disorders, such as erythemas and eczemas, and the whole body more inclined to be affected by the sudden cooling off of the temperature, which very frequently takes place after sunset. In consequence of the rapid absorption and the simultaneous diminished muscular action of the intestinal tube, its movements become less energetic; its thickened contents are propelled slower, becoming harder all they time, as they proceed onward; the bile becomes thicker, and so does the mucus which is secreted by the mucous glands of the bile-ducts, thus causing stagnation and enlargement of that organ. Constipation—bilious colic, as it is termed by the country people, but which in reality is only a symptom of the catarrh of the intestine existing—and often dysentery emanate from this state of affairs and nearly all spring and summer give the physician a large share of work. The popular saying is, "the liver does not act." This is only partly correct. It really acts as well as it can under such circumstances, but it is impeded in expelling its products as rapidly as required. The stagnation of bile in the liver and the distention of the finer ramifications of the bile-ducts in consequence, lead easily to venous congestion of that organ and other affections which will be mentioned hereafter. I have no doubt that it is the primitive cause that nearly all persons who have lived for a length of time in a tropical or subtropical country, have a larger liver than those of a Northern latitude. The most frequent disorder following the above-described state of things, is intestinal and gastro-intestinal catarrh. These are the cases in which the old prescription—calomel or blue mass and quinine—has at all times achieved such brilliant triumphs; the two former, by their stimulating effect upon the nerves of secretion, increasing the products of the mucous glands and making them and the bile more liquid, the latter by increasing the muscular tonus of the intestinal tube. Unfortunately the remedy can only correct the disorder for the time being, but cannot prevent the same causes from reproducing the same effect. For this reason the only way for people to hold their own during the long and hot summers is to take mild purgatives from time to time. My favorite remedy is the salts of the thermal springs of Carlsbad, in doses of from four to six drachms, taken in the morning an hour or two before breakfast. This is a mild purgative and does not irritate the intestines, even if taken for a length of time. I must state here, although it is in contradiction to high authorities, such as Trousseau and others, that all drastic purgatives, such as aloës, gamboge, scammony, jalap, are injurious and make matters worse. The different so-called "antibilious" pills do more for a physician, to keep him busy than the disease proper would do. The popular belief is that a purgative should be taken

from time to time, and what is correct enough in one way is only made wrong by the wrong remedy. The irritation which these drastic substances produce upon the mucous membrane of the intestines is very often followed by more serious consequences, if taken repeatedly within a short time.

We then have to contend with chronic intestinal catarrh, stubborn habitual constipation (which these pills fail to overcome by that time), a low state of digestion, and often a still lower state of spirits in our patients. In many of these cases the salts of Carlsbad render excellent service; in others I obtained the best results by the administration of Bretonneau's belladonna pills. My prescription is somewhat different, however. I give one eighth grain of the extract of belladonna and of that of nux vomica twice daily, giving at the same time to my patients the direction to live entirely on liquid nourishment. My patients generally got along well under this simple treatment. Icterus I have but rarely observed in these cases, even where the liver was considerably increased in size, although, for obvious reasons, we might expect that symptom to present itself. One case of the most singular state of perversion of a distant plexus of nerves, in consequence of the above disorder, I had the opportunity to observe not long ago. A physician of this city was attacked by most violent pains in the bladder, which were so excruciating as to make it impossible for him to get one moment of rest. The attending physicians did everything within their power to obtain relief, but all in vain. Four days and four nights the patient had passed without one minute of sleep and almost mad with pain. Morphine, which had been administered to him, had produced the most alarming effect; instead of quieting, it had led to a maniacal state, with hallucinations, muscular excitement, etc. At this juncture the father of the sick gentleman came to request my attendance. I attended a consultation with the other physicians, and found, upon examining the patient, the pulse and temperature almost normal; the liver increased in size; the small intestine somewhat tender and distended by gases; the cæcum and colon also distended by gases, and containing some fecal masses; the urine free from albumen or anything abnormal, when examined by the microscope and by chemical tests. The sick gentleman was considerably emaciated; he had suffered for some months from constipation, malaise, and loss of appetite, and had frequently had recourse to purgatives. A convulsion took place during my presence, which passed in a short time, however. It was evident, to my judgment, that the nervous perversion was simply in consequence of a chronic catarrh of the intestines, in which the pain emanating from the splanchnic nerves had radiated in the direction of the hypogastric and vesical plexuses, thus causing, at a distance from the real seat of the disorder, and at a part which otherwise was in a perfectly normal state, the most violent symptoms. Blue mass and quinine had a most excellent effect in this case. About four hours later the pain had subsided, and the patient fell asleep without any further remedy, the fatigue of the nervous system predominating now over the nerves, that previously were in a state of perversion and excitement. I have often seen cases of intermittent neuralgia extending over a considerable area of the body but this was not a case of that order. The other physicians, suspecting it to be such, had given quinine in sufficient quantity to overcome it, had such been the case. In the clinics of Europe and the United States I do not recollect to have seen a case as above described, although I have seen a great many cases in which diseases of the uterus, ovaries, the bladder, etc., produced the most violent spasms of the stomach, with obstinate vomiting and other symptoms of a severe affection of the apparatus of digestion.

Dysentery.—One of the old and yet one of the highest authorities (Cullen), in speaking of this disease, expresses the opinion that it arises from the same causes which I mentioned above as leading, in the first instance, to intestinal catarrh. Cullen, in short, considers dysentery produced by constipation first, and mechanical irritation afterward. There is everything in favor of this view. I can say from my own observations that I have not seen any cases of dysentery here, or anywhere, which were not preceded by constipation. This disease occurs here almost at all times of the year, but its frequency increases with the advent of the hot weather. The hottest summers always have brought to me the largest number of cases, while the cooler ones showed comparatively few. For this same reason I think this disorder should not be classed among the diseases of infection, as some high authorities do.

Above I have enumerated the principal causes of intestinal catarrh, as they present themselves daily. I mentioned, besides, the well-known fact that people who have sojourned for a number of years in a tropical or subtropical country have the volume of the liver increased. This increase is not a hypertrophy or hyperplasia of that gland. Persons who were affected that way to such an extent as to be seriously inconvenienced by it, and whom I sent to Carlsbad, in order to take the waters of its famous springs, returned greatly improved, the organ having again attained almost its natural volume. I wish it to be understood that I say "almost," because there remained always a slight increase. This increase is the consequence of stagnation first, then venous congestion and dilatation of the finer ramifications of the bile-ducts and portal vein afterward. If there existed proliferation of the intercellular tissue or real hyperplasia, the cure at Carlsbad would hardly reduce the size of the organ to such an extent. Whenever the passage of the blood through the liver is impeded, hyperæmia of the mucous membrane of the intestines is the unavoidable consequence, and principally that of the rectum and colon, their veins being the most distant, having no valves, and being more exposed to pressure by solid contents. This alone would hardly produce dysentery as frequently as it occurs in this country; it is due in great part to the substances which form the principal alimentation of the large majority of the people. These consist of corn-cakes (tortillas), beans, and Cayenne pepper. To prepare the corn-cakes, the corn is ground on a flat stone by means of another stone, which is held between the hands of the tortillera (the woman that makes the cakes). This grinding is very imperfect, and leaves a great deal of substance upon which neither the gastric juice nor any other intestinal secretion can have any solvent power. A small part is digested, and most of it remains as ballast, as Liebig calls it in his "Letters on Chemistry." The beans are not quite as heavy a task, but they also leave a considerable proportion of undigested residue, which the intestines can move forward with some difficulty only. The substances are ingested mixed with sometimes an excessive quantity of Cayenne pepper, which, by its constant contact with the mucous membrane of the intestinal tube, acts as a powerful irritant. Under these circumstances it is easily comprehended why intestinal catarrh and dysentery are so frequent. I have made it a rule to inquire of my patients affected by dysentery whether they had eaten fruits to excess or in an unripe state, and have invariably received a negative answer. Trousseau, as my readers probably are aware, denies that eating fruits produces dysentery, and I have had sufficient opportunity of convincing myself of the correctness of his views. As to the epidemic of dysentery which befell the German army that fought the battles around Metz, and later besieged that fortress, the problem, whether it was a real epidemic or whether it was caused in the manner above stated, is not yet solved to my satisfaction. An army of nearly half a million of men making forced marches day after day under a hot sun, living on rough nourishment, perspiring heavily all the time, not having always water to drink, finding scarcely the time to

attend to that most important function, defecation, and with all this the fatigues of battles, patrol duty, etc., may well have a large proportion of its men affected by dysentery when all the conditions for its production are existing. The question still is, whether it was communicated from the sick to the healthy, whether its character was epidemical. I speak of catarrhalic dysentery and not of diphtheritic, the origin of which is unexplained to me, since a small proportion of cases always occurs with the many of the first-mentioned class. But even in these I have not seen the disease communicated to nurses or attendants.

Those I have had to attend to showed considerable destruction of mucous membrane, pieces of which were evacuated in a necrosed state. There was always considerable fever—a symptom much less prominent in the catarrhalic form—and prolonged ulceration. In managing cases of dysentery of any kind, I devote principally care to the thorough evacuation of the bowels, and if one purgative does not accomplish this, I repeat it the next day. My favorite remedy is the neutral solution of the citrate of magnesia (one ounce citric acid to six drachms magnesia) in eight ounces of water. To children above two years of age I give from two to four ounces of this solution. This acts thoroughly without irritating the intestines. Only when I am satisfied that the bowels are thoroughly evacuated do I administer opium or morphine. To small children, instead of this, I give a solution of hydrate of chloral by the mouth and by the rectum. Enemas of a solution of boracic acid with acetate of lead and opium tincture have often given me the most satisfactory results. In many cases I have resorted to the old remedy, the decoction of simaruba bark (one ounce in twelve ounces water), which is still one of the most valuable remedies in the treatment of this disorder. Blisters to the abdomen and cups or leeches I have never found any use for. I saw lately a case, however, in which a would-be physician had applied a blister nearly ten inches square to the surface of the abdomen, producing thereby the most violent tenesmus of the bladder, nephritis, and hæmaturia. I am glad to be able to say that the patient recovered—from the effects of this barbarous treatment first and from his dysentery afterward. It is hardly necessary to mention that the patient suffered severely before I succeeded in quieting matters.

The most serious and not very unfrequent consequence of dysentery, principally if prolonged so as to lead to deep ulceration, is the formation of abscess of the liver. All the cases of this most serious affection which have come under my treatment could be traced back to dysentery, with the exception of one, which was of traumatic origin, the person having fallen from a considerable height, breaking his arm at the same time. Frerichs, in his work on "Diseases of the Liver," gives quite a number of causes, which, according to his observations, produce abscess of the liver; but, as I stated above, those observed by me came in the wake of dysentery. The result has been fatal in all cases, except one, in which the continued use of the Carlsbad salts, together with repeated applications of leeches over the region of the liver, and afterward frictions with the ointment of iodide of mercury, led to a gradual absorption of the pus and the formation of a cicatrix, which now, after four years, can be felt. I have not been so fortunate as to find the opportunity to evacuate these abscesses by means of the trocar or the aspirator. I made an unsuccessful attempt to do so in one case; but the aspirator drew nothing except a few drops of very thick matter. The relatives of the patient did not permit the aspirator to be introduced at another point, and I learned shortly afterward that he had succumbed. My experience has been consequently most discouraging in this disease.

Monterey, Mexico, January 8, 1885. EDMUND GOLDMANN.

MEDICAL FEES.—A fee in the hand is worth two in the book.

POISONOUS PUMPKIN PIE—CHROME-YELLOW POISONING.

To the Editor of The Medical Record.

SIR: I was summoned recently to attend four persons of one family, who had been seized, without assignable cause, three or four hours after dinner, with nausea, vomiting, and in two cases, purgation. An analysis of the influences to which these persons and another member of the family had been severally subjected led me to infer that a pumpkin pie, partaken of at dinner, was the cause of the disturbances.

I was told that the pumpkin-paste of the pie was of an inordinately yellow color, but withal very insipid. I was thereby led to the further inference that some noxious substance had probably been used by the confectioner to give an appearance of richness to the dish.

The statements contained in the paragraph in the current issue of The Medical Record on chromate of lead as an adulterant appear to me to give considerable warrant to the belief that the cases mentioned above were cases of poisoning by that substance.

Your obedient servant,

C. PITFIELD MITCHELL.

22 East Thirty-fifth Street.

[The amount of chrome-yellow required to color pie would not be poisonous. The poison is more likely an aniline color. Lemon pies colored with this substance have caused toxic symptoms.—Ed.]

THE HEALTH BILL.

To the Editor of The Medical Record.

SIR: As a member of the Committee on Federal Legislation at the recent Conference of State Boards of Health, held in Washington, may I ask the favor of a few lines in order to reply to some objections brought forward by your correspondent, A. S. Carroll, M.D., in criticism of the bill reported by the above-named committee, and submitted to Congress by direction of the Conference.

The first objection raised is to the form of appointment, that is, by the President with confirmation by the Senate. To this it may be replied that there is no other way in which the members can obtain a national position. The General Government would not confer upon a body selected by the various State boards of health the national powers with which the proposed organization must be clothed. My own knowledge does not allow me to assert, as your correspondent seems to imply, that the State boards are so largely made up of politicians as to be unsafe material from which to construct an efficient central authority. There is very little in the work of a State board of health to invite the presence of the political schemer, and my own belief is, that the members of these boards throughout the country are the most trustworthy collection of sanitarians from which to select a national organization. They have the necessary training and experience.

The objection that the tenure of office is not limited, is not well taken. The members of State boards have definite terms of service, and would cease to be members of the National board whenever they failed of a reappointment upon the State board, so that there is little probability of any individual enjoying, for an unlimited term of years, "the potential profits of the proposed machinery," whatever this may mean.

Thirdly, it is suggested that some person not a sanitarian may become a member of the board, of the executive committee, or even be selected for the important position of executive officer. I will answer to this, that the first State board of health organized in this country—that of Massachusetts—has never felt the need of a statute protection against the lay faculty of educated common sense; rather it has been welcomed, and I am very certain that the board has profited thereby.

Its successive health officers have been physicians, and it has never occurred to the board to put in jeopardy important functions by any other selection; nor do I believe that a national board would have a less well-defined sense of the measures essential to self-preservation.

One word as to the composition of the committee that framed this bill: With one exception, the Hon. E. Brooks, of the State Board of Health of New York, the members were all physicians, now or formerly executive health officers in their respective States and cities, presumably jealous of their claims as medical officers of health, and yet I venture to assert that probably not one of them saw the necessity of inserting in the draft a provision, that none but competent persons should be appointed by the President or confirmed by the Senate; but all felt that men now safely trusted in their respective States with large powers for the protection of the public health would not of necessity fail in a wider sphere because their responsibilities had been honorably increased. While admitting the force of an objection to the size of the proposed board, the difficulties in the way of forming a truly representative board without direct State representation seem insurmountable; but, as the board as a whole meets but once a year, and has authority to bestow any power it will upon an executive committee of convenient size, the objection cannot, I think, outweigh very manifest advantages. Subject to annual election, the executive committee cannot properly be designated as either permanent or arbitrary.

A more careful reading of the bill will, I hope, convince your correspondent that there is the least possible provision for patronage of any sort.

The section providing for enforcement of rules, framed by the National Board, in States where no adequate quarantine regulations exist, was omitted in deference to grave doubts expressed by prominent lawyers as to the constitutionality of such a provision.

H. P. Walcott, M.D.,
State Board of Health L. and C., Massachusetts.

PURPURA HEMORRHAGICA.

To the Editor of The Medical Record.

Sir: In your issue of January 3d, page 9, appeared an article under the above title by Dr. J. H. Ziteke. I read with absorbing interest the article, believing as I do, that the heretofore rare disease is becoming more common in this country.

To Dr. Ziteke the thanks of those among us who do not believe in using alcohol, except when the indications are complete, are due.

According to Rigal and Cornil (quoted in Duhring's "Diseases of the Skin," 3d ed., page 363), purpura hemorrhagica is the result of debility following nervous exhaustion, the hemorrhage being due to irritation of the sympathetic nervous system, or upon diminished action of the vaso-motor centres.

Alcohol (Farquharson, "A Guide to Therapeutics and Materia Medica," page 130) paralyzes the sympathetic nervous system, and its chronic abuse causes nervous tremors and debility. An analysis of Dr. Ziteke's case, viewed in the light of the above authorities, would be as follows: Mr. Johnson M——, as a result of the continual abuse of alcoholic drinks, exhausted his nervous system; debility followed, and the sympathetic nervous system being continually irritated by the alcohol, purpura hemorrhagica ensued.

It is more than probable that every case of purpura hemorrhagica can be explained by this modern etiological view. Any disease which, during its course or toward its termination, produces nervous exhaustion and great debility becomes the predisposing cause, and should the sympathetic tract or the vaso-motor centres be irritated, both predisposing and exciting causes would be present to produce the disease. Thus we have it during the course of the severest forms of typhus fever, rubeola, and in the hemorrhagic form of variola, in all of which it proves invariably fatal. I have also met with the disease upon one occasion occurring as the sequela of a very severe form of typhoid fever, with protracted convalescence. This patient (upon reference to my journal) had the first premonitions of purpura hemorrhagica four and a half months after he was free from fever, and three from the time he first could be permitted, and indeed was able, to go out. He had the characteristic purpuric eruption upon his feet and legs, forearms and hands, and a few extravasations upon the left side of the chest over the ninth and eleventh ribs, and in a line with the axilla. These spots varied in size from that of a pin-head to that of a twenty-five cent piece. His gums were soft, very vascular, and although they would not bleed, could be made to do so by merely pressing upon them. He lost daily for a month about three ounces of pure arterial blood from his bowels. He finally, after a sickness of two and a half months, recovered. Toward the termination of fatal illnesses where the above causes are in operation the same disease is produced, *i.e.*, Bright's disease, pulmonary phthisis, syphilis, pernicious anæmia, etc.

Frerichs (Wood's Library of Standard Medical Authors, vol. i., page 147) has placed on record a case where it appeared toward the termination of acute atrophy of the liver; and again (vol. ii., page 64), where it appeared toward the end of acute fatty degeneration of the liver. A. Verneuil ("International Encyclopædia of Surgery," vol. i., page 318) has met with the disease following the course of hepatic disease, malaria, diabetes, scurvy, and leucocythæmia. Erichsen (vol. i., page 913) believes that the disease occurring in the course of scurvy, chronic jaundice, and albuminuria, is due to the *morbid state of the blood*, in consequence of which its coagulability is diminished or lost. But he is inclined to admit that the solid tissues of the body rather than the blood is at fault, and "that one element in the disease is certainly a want of proper contractility of the arteries."

Niemeyer (vol. ii., page 455,) says that the disease appears in healthy, robust subjects who indulge freely in spirituous liquors, and is due to the intense fluxionary hyperæmia. He further believes that the *nutrition of the walls of the blood-vessels* is at fault in the purpura of the severe exanthemata, scurvy, etc. In conclusion, I desire to say that should the etiological factor in purpura hemorrhagica prove to be nervous exhaustion, one cannot help, after reading Dr. J. Leonard Corning's book on "Brain Exhaustion," or his most admirable paper with the same title (*New York Medical Journal*, December 29, 1883, page 712), having the greatest hope in its remedial treatment by the fluid extract of coca.

Very sincerely yours,
T. W. Lauterborn, M.D.

Vol. 27, No. 6 — New York, February 7, 1885 — Whole No. 744

Original Lectures.

VALEDICTORY ADDRESS

Delivered Before the New York Academy of Medicine, February 5, 1885.

By FORDYCE BARKER, M.D., LL.D. (Edin.),

retiring president.

Fellows of the Academy: In now closing my official relations with the Academy, it is both a pleasure and a duty to briefly recall the more prominent features in its history during the period of this connection. I will also venture to offer a few suggestions, derived from my long experience in this position, as to some points relating to its future growth, its increasing usefulness, and its influence on the profession. As I know you will be impatient for the intellectual feast which is to follow in the address of my successor to this Chair, I shall be as brief as is consistent with a clear statement of the points to which I think it desirable to ask your attention.

It has been my good fortune to hold this position when the profession were becoming more alive to the importance of this institution, and more and more ready to contribute material aid for its growth and support. At the same time, there was a new development of mental activity in the profession, not only in this city, but all over the world, as demonstrated by great and important discoveries in science, and a wonderful increase and valuable additions to medical literature.

As I have referred to these facts more in detail in former addresses before the Academy, I will not detain you now by further allusion to them. I will only briefly refer to a few of the most notable events connected with the Academy, during my administration.

First to be mentioned, is this new and commodious hall, which could not have been built except for the munificent donation of one noble benefactor, Dr. Abram DuBois, and the contribution to the full extent of their hard-earned means by many others. We are rapidly out-growing our new hall, and must soon have another, as our library is now nearly filled. As I learn from Mr. Browne, our excellent Assistant Librarian, the Academy had when this hall was built, in 1879, about nine thousand volumes; it now has about twenty-five thousand volumes and fifteen thousand pamphlets. Its circulating department has about six thousand volumes, which our Fellows can take out of the library for consultation at home. In our journal room, open as is the library, for all who may wish to read in our rooms, there are two hundred and twenty-five medical journals, in all languages in which there is to be found a medical literature.

The Academy is greatly indebted to Messrs. William Wood & Co., and D. Appleton & Co., for large donations of their new publications, and I believe, to some foreign and other American medical publishers. We gratefully acknowledge the generosity of these gifts, and we feel assured that they were made from entirely generous motives. But we may be permitted to express the conviction that both publishers and authors will find it a wise business policy to place a copy of every new medical work in our library, as it has been estimated by a competent authority that one copy of every new good book in this library will secure the sale of at least ten more. The library is visited not only by the profession of this city, but by medical men from all parts of the country who come to this great metropolis. They have seen in some medical journal a notice of a book, but have not remembered who were the publishers; in coming to our library they examine it to see if it is what they want.

The next notable event in the history of our Academy since I have held this position, is its absorption of another very important organization, the Journal Association, which, to quote from a former address, "not only added largely to our library, but also to our moral and intellectual power."

The truth of history demands that the fact should be mentioned that, nearly two years ago, the Academy passed through the segment of a cyclone, but, like a good steamship driven over a sand-bank near a lee-shore, with its engines temporarily disabled, it escaped being hogged, its seams were not opened; its barnacles have been scraped off, its bottom has been cleaned, and it has since gone on its voyage with favoring winds and fine weather.

All who are familiar with its past history and who are unbiased by personal feeling or prejudice, must agree that the Academy has more nearly approached its avowed aims and its high purposes during the past year than in any former one since it was founded. It has had a larger increase of prominent men, and of young men of promise, than in any previous year since that in which it was organized, with the exception of the year when the Journal Association came into it. More than four times as many papers have been offered to me than there have been sessions to listen to them—as these sessions had been promised to previous applicants, months before; very many of these papers have been withdrawn, and I have afterward seen them, not only in the medical journals of this city, but in the journals of Philadelphia and Boston. It is bare justice for me to add that I have generally found them to be of such merit that I greatly regretted that the Academy could not have had the credit of their first publication.

The papers which have been read at our meetings, have been characterized by careful preparation, thorough research, original and often valuable hints as to pathological explanations and therapeutical indications.

Our discussions have been of such excellence that I am quite certain that every one carries away from our meetings either new suggestions or new information, which amply compensate for the evening pased in this hall.

In a scientific body like this, all discussions should express the results of mature inquiry, and a clear and forcible statement of the reasons which have led to positive practice. In some papers, the novelty of opinions advocated and the original methods of practice proposed, whether medical or surgical, may be so exclusively a matter of individual experience that all discussion must be necessarily limited at first to inquiries and *à priori* objections, founded on anatomical, physiological, or pathological grounds. Papers of this class should be the subject of a most thorough and searching examination; for they may be either mischievous, and their effect for evil must be effectually exposed, or they may possess positive value, which should lead to prompt acceptance and adoption.

To secure such discussion as will represent the most advanced knowledge of the Academy on any special topic, I have recently adopted a plan first introduced by Dr. V. P. Gibney. Writers of papers have been requested to send to a few of those whom they knew to have given

special attention to the subject, the points which it would suggest for discussion, printed on a small slip of paper, and especially asking those who held different or opposing views to take part in the discussion. They thus have time to arrange and formulate their knowledge of opinions, and the time of those present at the meeting is not wearily wasted in listening to crude, profitless, and digressive talk.

The reports of the Treasurers of the Academy and of the Board of Trustees have already been before the Academy. While its financial condition is now better than ever before, there still remains much to do. A few weeks since a Committee of Ways and Means was appointed, of which Dr. Gouverneur M. Smith is the chairman, to solicit contributions to pay off our only debt, a mortgage of five thousand dollars. They have worked with great zeal and enthusiasm, the Fellows of the Academy have responded with self-sacrificing generosity; the necessary sum has not yet been wholly secured, but the prospect of soon accomplishing this is most encouraging. We particularly need money for preserving our library by book-binding. It will be remembered that last year a generous sum was given for this purpose by a lady, who has in many instances shown that she is a warm friend to the Academy, as she is conspicuous for her readiness to aid every good work by munificent support. Many of our Fellows have also most liberally added to the beauty of the library in this way, and have rendered great service in the preservation of our books in good condition, which otherwise would speedily deteriorate.

I have long contemplated offering some suggestions on the present occasion as to the wisdom of a change in our by-laws relative to the duties and functions of the sections. Only one of the sections, that of Obstetrics and Diseases of Women, has kept up an active organization, done excellent work, and made regular reports to the Academy since my official connection with it. Two or three only of the other sections have reported their organization by the election of a chairman and secretary; and this has been all. Two have appointed a Fellow to read an original paper before the Academy, one of which, a most valuable paper, was read before us. The other, I have never been able to get, and as four years have now passed since that time, I do not think it very probable that it ever will come before the Academy.

The founders of the Academy did not contemplate making these sections independent societies for special work, but as contributing aids to the high aims of the central power. I had proposed to suggest such a modification of Article XVII., Section 2, as would assign to the sections functions similar to those of the Academy of Medicine of Paris. But we have not the time now to consider the details of such a change, and I leave the matter for future consideration by the Academy and my honored successor.

Neither did the founders of the Academy intend to absorb or concentrate in itself all the scientific work of the profession in this city. The whole spirit of its high aims and purposes indicates that, on the contrary, they desired to stimulate and encourage such work in every feasible direction. I hope the time is not far distant when the Academy will be so well endowed, that it may offer to all such societies as the New York County Medical Society, the Pathological, the Obstetric, and the Surgical Societies, and the youngest of all, which has begun its career with excellent scientific work, the New York County Medical Association, a home for its meetings free from all expense.

Our standing committees have always faithfully discharged their important duties, with one exception, and that is the Committee on Medical Education, which has had little to do, and it has just done this and nothing more.

I may now be permitted to ask if the time has not come when it should be one of the most important and useful of all of our standing committees, in carrying out one of the objects of the Academy as declared in our constitution, "the elevation of the standard of medical education." How can this best be effected, is the question.

It seems to me that a way is now open for this committee to do effective work in this direction.

For years the medical profession in all parts of the country have been agitating the question of separating the licensing power to practise medicine from the teaching power.

It is a subject of great importance to the profession, to our medical schools, and equally so to the community. It must be met and settled in a way that will be most effective for good, but this cannot be done at once. There are two ways by which this can be accomplished, but each would require time.

One way involves the division of the profession into contending parties, each most zealous to carry its point, heated controversies, which always provoke personal feeling and personal antagonism, an appeal for action of societies, and a struggle for majority votes not only in medical societies, but in securing legislative action—all of which would undoubtedly affect injuriously our medical colleges and lower the profession in the estimation of the public. Any good secured would be at a great and unnecessary cost. The public cannot understand medical controversies, except from what appears on the surface. A "doctors' quarrel" seems to the non-medical community like a fight between drunken men in the dark. The late Mr. Charles Dickens once related to me a story which he had heard of how Sidney Smith convulsed with laughter a dinner company at Holland House, by his description of a duel between two doctors. The mode of warfare was croton-oil on the tips of their fingers, trying to rub each other's lips.

Now, this question is one which belongs to the domain of reason, and let us hope, for the honor of the profession, that hereafter it will be confined to the region of argument, and that in due time it will be settled to the satisfaction of all who are actuated by pure motives and a desire to secure the best results. At the last meeting of the Academy, some resolutions were offered, but by the courteous consent of my friends, the mover and seconder of the resolutions, they were laid on the table for future consideration. I therefore feel that I have now the floor, and venture to throw out a few suggestions as to the other method of meeting this question.

In order that the standpoint from which I look at this subject may be perfectly understood, I will briefly state a few propositions which seem to me common ground upon which we all stand, and from which we must start.

Where charters for medical colleges can be easily obtained from State Legislatures, it is a duty which the profession owes to the public, as well as to itself, to protect the community from ignorant, unprincipled practitioners of medicine, who not only swindle their victims, but jeopardize health, and often sacrifice human life.

This is a matter of great difficulty, where each State is an independent sovereignty as to all such laws—where there is no central power to control action—and where personal freedom of opinion and conduct is zealously guarded as to everything which does not interfere with the rights of others, as regards health and property.

The interests of the medical profession are so closely allied with the medical colleges, that what affects detrimentally the one must reciprocally injure the other.

The profession has a perfect right to supervise the methods and exercise a controlling influence over those who by law are permitted the privilege of giving a diploma, which is effectually a licence to practise medicine.

All wise legislation must be based on a thorough knowledge of all the conditions which demand special law; it cannot be evolved from the inner consciousness of any one who has only the spirit, the zeal, and the genius of reform, but must be derived from the accumulated wisdom and experience of the past.

Mere examinations by a special board, who have had no previous training in this direction, no personal acquaintance with the mental characteristics, the habits of study, or the personal conduct of the candidate, would be as unsafe a test for admission to the profession as any objection that can be urged as to the present system. Injustice would be done to some, while flippant readiness in reply, which can be easily attained by a quick, bright mind by a few weeks of cramming, without either solid acquirement or sound judgment, would always secure success.

The experience of all countries has demonstrated the wisdom and necessity of examination by and the assent of the teaching faculties.

But in all other countries, except this, there is an additional protection to the profession and the public by the concurrence of another power.

In the Edinburgh University, and in some other medical institutions of Great Britain, this is vested in a special Board of Examiners. In France, this is under the direct control of the Government. The Minister of Public Instruction has not only the power of granting or withholding the diploma, but in addition, even in this so called Republican Government, he has the power of retiring any professor whose teaching is not abreast of the times. In Germany also, while the methods vary in different universities and in different constituent parts of the Empire, it is yet under Government control, which I believe is always exercised wisely.

Now I offer the suggestion that a committee of judicious, wise, and unprejudiced medical men, which would represent the best interests of the profession, the medical colleges, and the public, could frame a law, with the aid of competent legal advisers, which would combine the two methods, in accordance with the spirit of our republican institutions and the sentiments of our epoch, and thus save the profession from unfortunate and heated controversies, and from crude, hasty, and ever-changing legislation.

Would not the demands of the most progressive members of the profession be satisfied if the Regents of the University were empowered by law to appoint the Committee on Education of the Academy of Medicine a supervisory board of examiners for the medical colleges of this city, whose duty should be to make an annual report, not only as to the examinations for diplomas, but other details as to the instruction and education of the student? This committee should be enlarged to the number of the principal departments of instruction, and should serve without pay; for there can be no doubt that the best men in the profession, who have the time, would esteem it a high honor to serve on such a committee.

For the medical colleges in other parts of the State, there would be no difficulty in devising a method by which the regents would appoint men for the board of supervisory examiners who would be most satisfactory to all.

None except those who are well acquainted with the facts, can appreciate the immense advance which the medical colleges of this city have made within the past quarter of a century, in teaching and increased facilities for acquiring a thorough education in all departments.

I have also great pleasure in referring to two other schools, the Polyclinic and the Post-Graduate Medical School and Hospital, which have been doing great work for the more thorough medical education of those who have diplomas, and thus necessarily for the "elevation of the profession," within the past three years. I do not believe that one in fifty of the profession of this city have the least conception of what these schools are doing. If I expressed in moderate terms my estimation of the importance and value of their work to the profession of the country, I should be regarded by many as either carried away by my enthusiasm or prompted by personal considerations—so I will only say, go and see for yourselves. Medical men who come to this city, and who always keep up their professional interest, should not fail to visit and see what clinical teaching and clinical opportunities are found here, with all the equipments for their utilization, and they will be well repaid for the time given up for this purpose. This system of special clinical improvement originated in Germany, and nine or ten years ago I seized an opportunity to visit the most prominent of the policlinics in that country. Undoubtedly they have greatly advanced within this time, but I assert that then none that I visited were, either in clinical advantages or clinical teaching, on a level with our own at the present time.

I take the liberty of suggesting that it would be a wise and politic move for the medical colleges of this city, the New York Polyclinic and the New York Post-Graduate Medical School and Hospital, to take the initiative and invite the Committee on Medical Education of the Academy of Medicine to visit these institutions, study their methods and their equipments, and report the result of their observations to the Academy at its annual meeting, in January, 1886.

It must be obvious to all that this great improvement in medical education, far beyond the elementary teaching of former times, implies a corresponding elevation, not merely in the level of the average of the profession, but a still greater growth in the higher standards of medical science and literature.

Thus the inquiry is naturally suggested, What is the future of this Academy, what is to be expected from it, and how is it to be placed on the high plane where it should stand in reference to the profession, not only of this city and of this country, but of the world? A wise forecast will early plan to secure a result which it desires to attain.

While our educational institutions are steadily improving their facilities for training the young men who are about to begin their career, and our policlinics and post-graduate schools are more thoroughly preparing them for the higher grades of the profession, such an organization as our Academy of Medicine—in the great metropolis of the country—should be an ultimate centre, at which all those who have been long enough at work to find out their individual vocation, should have every opportunity to carefully study all the literature of past ages, and make original investigations in every possible field of medical science which can add to its importance. All short of this will be just so far a failure of the true mission of the Academy.

Thus far, which is only a beginning, the Academy has done its duty in bringing together most of the best men of the profession, and making them acquainted with the special ability of each—in collecting a most creditable library for consultation, research, and circulation—and in stimulating and bringing out good literary scientific work.

What the Academy requires in the future is:

First.—A large fire-proof building, with ample room for a library containing all the medical literature of past and coming times, and including:

Second.—A large hall for its meetings, and others for smaller societies and committees.

Third.—A large room for a museum, illustrating physiological and pathological anthropology, and which should include a craniological series, a pathological series, and a series of sections and dissections, illustrating topographical human anatomy, and a comparative anatomy series.

Fourth.—An anthropometric laboratory, provided with the best means of measuring human bodies, the faculties, and everything cognate to these subjects, and which should include a set of psychometrical instruments, and everything pertaining to the series.

Fifth.—A lecture hall, connecting with the laboratory, and fully equipped with apparatus for lectures and demonstrations of all kinds.

Sixth.—It should also have a thoroughly educated and trained pathologist, who should, by means of an adequate

salary paid by the Academy, be able to superintend all the scientific work and report on the specimens furnished to him; and also a first-class mechanic, skilled in brass and glass work; and a good, practical phonographer.

This is a broad scheme, which will require a very large endowment, but it is my firm conviction that it only outlines the future of the Academy, even if it demands a million of dollars.

The liberality of New York is as boundless as its wealth when convinced of the worthiness of its object. But large wealth is subjected to perpetual annoyance from solicitations, and to criticism from those who have some pet end to promote, which they deem the most important above all others. This kind of discipline trains wealth to the exercise of discrimination and judgment, and besides it has its own convictions as to how its surplus can best be employed.

The position of the possessors or representatives of great wealth in this country is peculiar and anomalous, and the thinking men of this class, and there are many, perfectly comprehend this.

There is no reason to suppose that there will be any exception in this country to the general experience of the world in the past, which is, that those who have but little or no property will greatly outnumber those of large wealth. Here lies the peculiarity and anomaly of wealth with us. Heretofore, property has protected itself through its representatives by monopolizing or controlling the law-making and the law-administering power. With us the condition of affairs, if not actually reversed, has certainly been brought within the possibility, if not the calamity, of absolute reversal, inasmuch as through universal suffrage, untrammelled by conditions of property, and absolutely (in theory at least) free elections, the control of all law-making bodies, and the appointment of all law administrations, have come to be possible with those "who have not" rather than "to those who have."

Property or its representatives, and more especially the representatives of very large wealth, are therefore exposed to dangers in the future with us, through arbitrary or destructive legislation, which have not existed or do not now exist anywhere else. The possessors of great wealth, in virtue of their superior education and knowledge of the use of methods, may be able to guard themselves in the future as they have in the past, but this will turn on the fact whether the great majority of such have the clear perception of the future and the sagacity to avail themselves of the two strictly legitimate methods for protection open for adoption.

The first is to bring to the masses, in whom all political power rests, a full realization of the fact that nothing so undermines the property of a state, or so quickly impoverishes the people, through the arrest of industrial growth, as the impairment, or the menace of impairment, of the rights of property.

The second is the demonstration by the possessors of wealth, by liberal contributions to every object that can benefit humanity, relieve suffering, prolong and preserve human life, improve education, aid scientific investigation, and promote a higher development of art, that it is a greater boon to the masses than it is possible to secure by any other means, as the past history of the world illustrates.

We have abundant proof that this view has been adopted by many in this city.

The foundation of the Astor Library and the Cooper Institute, are a corroboration of this statement as regards the past. The splendid gift to the College of Physicians and Surgeons by Mr. W. H. Vanderbilt, the munificent endowment of the New York Cancer Hospital by Mr. John Jacob Astor, and the generous and liberal contribution of Mr. Andrew Carnegie for a pathological laboratory in the Bellevue Hospital Medical College, are recent evidences of the correctness of my assertion.

Such noble examples are sure to be emulated by many others in the future.

The wonderful growth and development of this country is unparalleled by anything in the history of the past, and it is certain to go on in even more rapid strides for years to come. Its educational and scientific institutions will be placed on a corresponding plane, as compared with other parts of the world, with its industrial, its financial, and its political relations.

There is another point worthy of remark: Men of wealth, in common with other men of intelligence, like those devoted to literature or science, have a desire to be remembered after death. They have a dread of having their names and the record of their lives pass into utter forgetfulness or oblivion. To avoid this, the resting-places of the dead are everywhere crowded with cenotaphs and memorials. This is strikingly manifested, in some parts of the country, by the most expensive monuments and mausoleums of modern times. They crowd each other in some of our cemeteries to such a degree, that they lose all their individuality in their multiplicity, and the names which they are intended to keep alive are forgotten in the observations as to the comparative merits of the architect or stone-cutter who has erected them. The only question asked is, "How much did it cost?" and the only suggestion is that of vulgar wealth. "Yet all here," to quote from quaint old Sir Thomas Browne, "are but Babel vanities. Time sadly overcometh all things, while her sister Oblivion reclineth somniferous, making puzzles of Titanic erections and turning old glories into dreams."

The only lasting monument a man can build is the reputation he makes during life, and the memory of the benefit which he has, in some form or other, conferred on those who live after him.

> "For the good dead through the ages,
> Lingering in historic pages,
> Ever gleam and grow immortal,
> Unconsumed by moth and rust."

From all these considerations, I feel justified in expressing the belief that the ideal of the future of the Academy which I have given will at no remote period prove to be history. I hope to live to see it well begun, and I have the strong conviction that some now present will see it in full accomplishment. Some man of wealth, fully comprehending the importance of this Academy, not merely to the profession, but still more to the public, will esteem it a privilege to have his name prefixed to our new hall, by furnishing the requisite sum to build it, and perfectly equip and support it. Others will contribute the necessary amount to give their names to each of the special museums that I have mentioned, and others will place their names on an alcove in the library.

I here crave indulgence for one remark, the only one personal to myself:

I trust this evening will end on my part all official connection with any medical societies. The remainder of my life, except the time necessary for bread-winning, will be devoted to putting on record the results of more than forty years of study, observation, and experience, with the hope that this may be of some value to the younger men of the profession, and to doing all in my power to urge forward that future of our Academy which I have anticipated.

I have but a few words to add, before introducing my successor.

Some years ago, when elected to a similar honor in another society, I remarked, "Scientific societies seem to be governed in their selection of office-bearers by one of two principles: One is to confer honor on those who by their contributions to literature and science have won a right to it; the other is to select such as will most efficiently perform the duties which pertain to the office."

In the election of my successor, the Academy has most happily combined both of these principles. His literary and scientific work have won for him an envi-

able fame and high distinction, equally in this country and in Europe. His ability as a presiding and executive officer has already been successfully tested by his former service as President of the New York County Medical Society, and of the Medical Society of the State of New York. Thus he begins his career with a prestige which is a promise of great success.

I now have the great pleasure of presenting to him the "loving cup," on which his name has already been engraved, and which is to be transmitted to his successors in turn. It is ornamented with the symbol of friendship and love, and the sentiment, "May peace and love be multiplied unto us."

I Some years ago, the phrase was very current in the political world, "Let us have peace." It is as wise a sentiment for the medical as the political world. I sincerely hope that my successor will never have to qualify this with the paradoxical appendix, "Let us have peace, even if we have to fight for it."

ACUTE ATROPHIC PARALYSIS IN THE ADULT,[1]

With Report of Two Cases caused by Arsenical Poisoning.

By W. PAGE McINTOSH, M.D.,

RESIDENT PHYSICIAN BAY VIEW ASYLUM, FORMER RESIDENT ACCOUCHEUR MATERNITY HOSPITAL, BALTIMORE, MD.

Acute anterior poliomyelitis is rather a rare disease in the adult, if one is to judge from the literature on the subject. I have had cause to be somewhat surprised in looking over the works on diseases of the nervous system to find so little said upon the subject. This is doubtless owing to the fact, as I have just observed, that the disease seldom occurs after childhood. The two cases which I shall endeavor to describe, are, I take it, somewhat unique, at least as to their causation.

Case I.—Jennie P. W——, female, aged twenty-seven years. Family history shows no neuropathic diathesis. Patient suffered some time ago with an attack of muscular rheumatism, otherwise health has been fair, suffers at times from melancholia; attempted suicide once previous to present illness. She has miscarried twice (violence), and has two living children, whose health is good, aged five and six respectively. Present illness dates three years back. She tells me that after eating a hearty supper she was about to retire for the night, when she was taken with burning pains in stomach, radiating over abdomen, uncontrollable vomiting, the vomited matter being of a greenish color at first, afterward mixed with blood. She suffered from great dryness of mouth and fauces, with intense thirst; also had diarrhœa, passing bloody stools; later she had profuse flooding (metrorrhagia). Suffered much during night, and on attempting to stand the next morning she found it impossible to do so, her legs, as she expresses it, "gave out and folded up under her." She was confined to her bed for three months, being for a long time unable to keep anything on her stomach, suffering great pain over her abdomen, diarrhœa, fever, bleeding at nose and uterus. Upon quizzing her she told me that she thought her husband, or the man with whom she was living, had poisoned her. She certainly, without any assistance, gave the symptoms of a typical case of acute arsenical poisoning.

When seen by me she presented the following symptoms: General appearance indicated fair state of nutrition, appetite good; sleeps fairly well; suffers with slight headache; temperature and pulse normal; suffered no pain except occasionally slight pain in knees; seems to have good use of hands and arms; legs very small as compared to body, muscles very much atrophied, right leg measures at ankle six and one-half inches; left, six inches; above knee, twelve and one-half inches and twelve inches respectively. Could flex leg upon thigh, but could not extend well; could not stand; in fact, could make no effort tending to upright position. When seated legs hung dangling down like a flail, muscles flabby, skin glazed and branny to feel. Entire absence of sole reflex, also of patella tendon reflex, foot extended and slightly turned in, tending to the deformity known as talipes varus; could not flex tarsus upon leg, the action of tibialis anticus and perineus tertius being in abeyance, as were other muscles in this region. Cutaneous sensibility not impaired. Tickling soles of feet could be felt, but caused no retraction of foot, feet and legs objectively cold. No reaction of muscles of leg or front of thigh to strong induced current. Slowly interrupted voltaic current produced degenerative reaction in calf muscles, also thigh, none in flexors of leg. Functions of bladder and rectum not interfered with; sexual appetite normal; catamenial flow regular.

Case II.—Fred. M——, German, aged twenty-two; admitted to City Hospital, March 30, 1884. Family history good. Patient had enjoyed excellent health up to time of present attack. When admitted to hospital he stated that he was taken suddenly with vomiting about twelve o'clock on the previous night, and continued vomiting and retching until morning. Denied having taken anything to cause above. He appeared very nervous and much exhausted, trembling all over. Complained of excruciating pain in stomach, headache, and great thirst. Suspecting arsenical poisoning, he was treated accordingly.

March 31st.—Headache; tongue badly swollen, dry, and fissured; eyelids puffy and itchy; face deeply red; bowels moved six or seven times; stools dysenteric in character, small in quantity, and very fetid; much straining and tenesmus; tender on pressure over abdomen, especially in epigastric region; no appetite; eyes very bright.

April 1st.—Rapidly losing flesh; paralysis of forearm and hand on both sides; tongue continues swollen, and is now covered with aphthous patches and small ulcers, as is also the inner side of cheek; scaly eczema on face; abdomen quite tender; still passes blood at stool.

April 5th.—Both legs paralyzed; from this to time of leaving almost entirely helpless; cannot extend hand or forearm, or use legs; mouth better; eczema disappearing; acknowledged taking five cents' worth (about a drachm) of arsenic, which he had bought to kill rats, with suicidal intent. Left hospital, April 14th.

I am indebted to my friend, Dr. Watkins, for notes on case while at City Hospital.

Patient came under my charge July 20, 1884. General condition at this time: Pulse, 100: temperature, 98⅘°; anæmic, complains of cold, anorexia, insomnia, and inability to use hands or feet; some pain in knees; no impairment of cutaneous sensibility; pupils equal; movements of eye-ball, vision, taste, smell, articulation, and swallowing normal; no trouble with bowels or bladder; can raise arm and flex at elbow; cannot close hand or flex fingers; tendon reflex absent at wrists on both sides; hand hangs perfectly limpid (wrist-drop); no reaction whatever to faradic current; slight reaction to slowly interrupted voltaic current; supinator longus acting best; forearm better than arm; legs very small from atrophy of muscles and adipose tissue; muscles soft and flabby; cutaneous sensibility slightly increased; skin reflex, very much exaggerated; can make no attempt to stand up; feet extended; ligaments of ankle-joint flaccid; slight voluntary motion, being able to flex tarsus just a little; cannot move toes; feet hang helplessly when he sits; tickling soles of feet excites skin reflex; sole reflex and patella tendon reflex absent on both sides; sexual reflex good.

No muscles in legs react to induced currents. Inter-

[1] Read before the Clinical Society, December 5, 1884.

rupted voltaic current from twenty-four cells causes some reaction in muscles of thigh and slight reaction in muscles of calf. *Reaction of degeneration.* The same current causes no reaction in anterior tibial group or peronei.

Patient under observation till September 1st. No perceptible improvement.

Etiology.—Sex and heredity seem to exert no influence. By far the most cases occur in childhood. Exposure to cold, injuries to back, exanthematous diseases, debility—all play their part. Loomis gives malarial poisoning as a cause, and from observations I have been able to make, I think arsenical poisoning may be enumerated among the causes. No authority that I have been able to consult mentions arsenic as a cause. Bartholow quotes Sklarek as having attempted to demonstrate that arsenic decidedly impairs sensibility, leaving the motor functions untouched. The same authority states that Ringer and Murrell found the observations of Sklarek to be incorrect, they having found the motor paralysis precede the sensory disturbances in the frog poisoned by arsenic. Hammond, Rosenthal, Bramwell, Charcot, and Buzzard do not mention arsenic. Leyden makes the following observations:

"Paralysis resulting from arsenical poisoning has been long observed. Leroy d'Estable reports several such cases. The paralysis generally affects the lower extremities, and is attended during its development with pain, tremor, and muscular weakness; occasionally the upper extremities are affected. As a rule, *motility* and *sensibility* suffer alike, though the former more extensively than the latter. The paralysis develops *slowly*, but cases are on record where it occurred rapidly following the external use of arsenical preparations. In addition to the paralysis there is frequently a burning pain and tremor affecting the extremities. The paralysis may exist for from four, six, to ten months. Anatomical investigations have failed to locate the lesion in arsenical paralysis, but the symptoms and distribution of the paralyses point to the existence of peripheral neuritis. Experiments on animals show that arsenic easily excites inflammation of the nerve-trunks, which may then extend to the spinal cord" (Leyden: "Clinic of Diseases of Spinal Cord," vol. ii., p. 296).

The paralyses here mentioned present no points of similarity to poliomyelitis; on the contrary, the slowness of their occurrence, the affection of sensibility alike with motility point to a wide difference; they are of service to us, however, in showing the power of arsenic to produce cord lesions.

Pathology.—Microscopical examination has, thus far, failed to decide whether acute poliomyelitis is an interstitial or parenchymatous inflammation; the weight of evidence is in favor of the latter.

It is essentially in the anterior horn of gray matter that the pathological changes occur, and has been described by Vulpian, L. Clarke, Charcot, Damaschino, and others. Buzzard quotes the following observations from these authorities:

"Under the microscope, at an early stage, areas of inflammation are found in the gray substance of the anterior horns, especially in the lumbar and cervical enlargements of the cord. In these areas of disintegration the substance is soft, friable, and interspersed with numerous granulation cells, the blood-vessels overcharged, and there is increase of connective tissue with its nuclei. The large multipolar ganglion cells have, in great part, entirely disappeared, whole groups having vanished, whilst of those that remain some are degenerated and atrophied, others undamaged. The nerve-fibres and axis cylinders within the areas of softening have also disappeared. The anterior horn, as a whole, appears wasted. There is often overgrowth of connective tissue, with wasting of nerve-fibres in antero-lateral column.

The anterior roots show signs of degenerative atrophy.

Observations made years after the attack show much firm connective tissue, thickened blood-vessels, together with large numbers of corpora amylacea. The muscles most seriously affected loose their transverse striæ, and are infiltrated with oil globules. The interstitial fibrous tissue in some fibres shows simple atrophy, in others is normal. In the young, bone growth is either arrested or else progresses exceedingly slowly.

Symptoms and Course.—In the infantile variety the trouble may begin in one of three ways: The child may retire in apparent good health. On awaking in the morning he can't walk. A group of muscles or a number may be paralyzed. Again, after one or several attacks of fever, with vomiting, thirst, delirium, convulsions, when these pass off he is found to be paralyzed. The third mode is when the trouble creeps on so insidiously that we are not aware of its presence till our attention is called to it by the deformities. We at times see children of some size thus deformed, and the parents can't tell how it began.

In the adult the "dominant unique exclusive symptom," as Charcot expresses it, is the trophic muscular lesion. The patient has probably suffered from traumatism, fever, or poisoning, which is followed by extremely rapid loss of power in the limbs. On testing the paralyzed muscles with electricity, we find that their faradic excitability is lost, or very much lowered. Duchenne was able to observe a case on third day of attack. On fifth day the electrical excitability was impaired, and was lost on seventh. Müller, who observed a case on first day of attack, found that the faradic muscular excitability still persisted when the nerves had lost theirs. On fourth day faradic excitability was lost for nerves, that of muscles on fifth and sixth. In paralysis of the lower extremities, the reflex from sole of foot is generally lost, as is patella reflex when muscles of front of thigh are affected. One or all of limbs may be affected. Duchenne found only five cases of general paralysis out of a total of sixty-two observed. Sensibility is generally not impaired. Functions of rectum and bladder not interfered with.

Differentiation.—When upper extremities are involved we find it necessary to differentiate from hypertrophic cervical pachymeningitis. This will cause paralysis with wasting, which very much resembles poliomyelitis. In the latter however, the process is rapid, and the highest degree of paralysis is reached at once. In pachymengitis the course is slow, occupying weeks, the condition getting progressively worse, the posterior roots being involved; there are also marked sensory disturbances, darting pains in extremities, with more or less cutaneous anæsthesia.

Injury to a mixed nerve will produce paralysis with wasting, and the nerve and muscle, when tested, will show the reaction of degeneration just as in poliomyelitis; but the lesion is found to be limited to the district of the nerve; cutaneous sensibility is also affected. A tumor pressing on anterior roots can only be told by its mode of onset.

So far as I am aware, no one has seen proper to draw the line between multiple neuritis and poliomyelitis. I have been so fortunate as to have a case of this trouble in the same ward with one of my cases of poliomyelitis, and I have been forcibly impressed with the similitude existing between the two affections. My esteemed friend and former teacher, Professor A. B. Arnold, has also been so kind as to furnish me with some data bearing upon multiple neuritis. "In this trouble we have motor paralysis, bilateral and symmetrical, implicating in the beginning either the upper or lower extremities." In the case I have under observation the lower extremities are paralyzed, the patient having no use of legs at all. The right leg was attacked two weeks later than left. The paralysis was preceded by pains in the limbs which continued; subsequent to the paralysis the pains are of a darting, shooting character, radiating in a centrifugal direction, also paræsthesia (sensation of formication, chilliness, and a feeling as if affected limbs were asleep), also

complains of a feeling as if water was running on skin, atrophy is rapidly developing in affected muscles, which show reaction of degeneration. The reflex tendon phenomena cannot be elicited, the skin reflexes arediminished; there appears at this time to be a hyperæsthetic condition of skin. I am led by the authority above quoted to believe that anæsthesia will supervene later, as will the trophic disturbances of skin, now beginning, into thickening pigmentation, and a glassy shiny hue. Cannot say if this patient had fever, but she says not. The mode of onset, sensory disturbances with later development of atrophy.

Prognosis.—Though not shortening life, the nature of the lesion—a destruction of ganglionic cells, with sequelæ—precludes idea of recovery.

Regression may, and does begin, but is very rarely complete. Reconstructive metamorphosis advances most rapidly in muscles which do not entirely lose their reaction to induced currents.

The power of responding to volitional impulses frequently returns long before the muscles will respond to the faradic current, as in one of the cases noted.

Treatment.—*Theories* are as thick as stars in night's diadem, *facts* as scarce as medical specifics. Absolute rest, light diet, counter-irritation, with constant current to increase warmth and nutrition of muscles. The faradic current probably does harm by increasing instead of lessening deformities.

CONTINUOUS TRACTION IN THE TREATMENT OF POTT'S DISEASE.

By JOHN F. RIDLON, A.M., M.D.,

ASSISTANT ORTHOPÆDIC SURGEON TO ST. LUKE'S HOSPITAL AND OUT-DOOR VISITING SURGEON TO THE ORTHOPÆDIC DISPENSARY AND HOSPITAL, NEW YORK.

THE *Boston Medical and Surgical Journal*, vol. cxi., No. 1 (July 3, 1884), published an article on "Extension in the Treatment of Diseased Vertebræ," by Buckminster Brown, M.D. The principles advocated accorded with theories held by me for some time, but not put into practice from lack of the right case under the right circumstances. On July 16, 1884, the case presented.

Patient female, seven years old. Hereditary history good. Four months ago her neck began to grow stiff, and soon head began to droop forward. No complaint of pain, and no crying at night noticed. The condition increased. The general health remained fairly good.

Examination.—The chin rests on the sternum, and at times is steadied by the hands. Voluntary movement of the head is impossible. Attempted passive movement in any direction elicits an anxious look but no complaint of pain; and the head is found to be held absolutely rigid by muscular spasm. There is a sharp angular kyphos at the third cervical vertebra. No evidence of abscess. The patient was put in bed on July 19th, a Sayre's collar was applied, and from it a cord passing over a pulley at the head of the bed, which was elevated, and a ten-pound weight attached. It was soon found that the patient would slide up in bed till the straps from the collar struck the pulley and released the traction. A harness was then arranged, of webbing around the waist and over the shoulders, and passing to the foot of the bed, where it was fastened. The appetite was good and the sleep normal. From this time the case progressed favorably. The muscular spasm relaxed; the chin left the sternum and the kyphos diminished. By the end of six weeks, voluntary rotation and flexion were possible to a considerable degree when the patient was lying in bed.

By November 15th, four months from the beginning of treatment, the deformity was entirely reduced, and motion free in all directions when the head was supported. When support was removed, however, the head drooped forward, and the patient caught the chin in her hands and complained of the motion. A support was then applied consisting of a modification of the H. G. Davis brace. The upright pieces of steel, instead of stopping opposite the lower borders of the axillæ, were carried up along each side of the spine, carefully moulded to the surface, and up over the posterior surface of the head to the occiput. From here a strap was carried around the forehead, and another downward to form a chin support. The chin support was removed at meal times, and has recently been removed altogether. Up to the present time there has been no return of the deformity, and the possible voluntary motion has increased.

I have followed one other case, but with less satisfactory result. During the vacation of Dr. Newton M. Shaffer, I commenced the treatment of a similar case in a like way in his service at St. Luke's Hospital. The hereditary history was not clear, a brother having died of meningitis, and the case was complicated with an abscess. The case improved, however, but the kyphos could still be distinctly felt when Dr. Shaffer returned. He did not approve of the traction treatment, and I put the case in Dr. C. F. Taylor's spinal brace and chin piece, with Dr. Shaffer's ball-pivot joint. The kyphos has slightly increased in size, but the patient has no pain, and prefers the brace to traction in bed.

Observing these two cases, I have been led to believe that in certain cases traction, as in hip-joint disease, will relieve reflex muscular spasm and pain more quickly, and give a better result as to deformity, than will fixation alone.

CAUTION IN THE USE OF COCAINE.

By JAMES L. MINOR, M.D.,

NEW YORK.

DR. KNAPP, in the New York MEDICAL RECORD for December 13, 1884, first called attention to the precaution which should be observed in the use of the new anæsthetic. His reasons are based upon the symptoms presented by the two following cases:

CASE I.—Six minims of a four per cent. solution of cocaine were injected close to the posterior segment of the globe. Anæsthesia was complete and the operation successful, there being no disturbing element in the recovery. During the operation, however, it was noticed that the patient became pale.

CASE II.—Five minims of a three per cent. solution of cocaine were injected beneath a sebacious tumor of the lid. Anæsthesia was complete, and the somewhat laborious operation was satisfactorily completed; but, during the operation, the patient became as pale as a corpse, felt faint, asked repeatedly for drinks, and was covered with cold perspiration. All of these disagreeable features passed off in fifteen minutes. Dr. Knapp, while recognizing the safety of injecting larger quantities of cocaine in other parts of the body, suggests that the vascularity of the orbit may allow quicker entrance of fluids injected here into the general circulation than elsewhere, and will hereafter be more cautious in the use of cocaine about the eye—will use one or two minims, and feel his way. The New York MEDICAL RECORD for January 17, 1885, under the head of "Disagreeable Experiences with Cocaine," refers to numerous communications from correspondents, relating more or less disagreeable or alarming experiences with this drug—some of which appear in its columns. Dr. E. S. Peck, of New York, has had the same experience as Dr. Knapp in operating for squint, under cocaine, in the person of a young lad. A four per cent. solution was used, and during the operation, was noted "increasing pallor of the face, together with a profuse, beady perspiration." This was at first attributed to apprehension or pain, but as no pain was experienced, it is thought to have been due to the drug.

Dr. George T. Stevens, of New York, injected four minims of a three and a half per cent. solution of cocaine

over the course of the rectus internus, preparatory to advancement of this muscle, in the person of a very nervous man. The operation was performed without pain, and ten minutes later the patient had convulsions, difficult breathing, loss of consciousness, and a livid face. All of these symptoms passed off in half an hour, and nothing out of the way could be discovered by a careful examination of the man, farther than dilatation of the pupils ad maximum on the operated side. He refers to Dr. Knapp's observations, and suggests that the proximity of the orbit to the large nervous centres may, in part, account for the disagreeable symptoms.

Dr. E. C. River, of Denver, Col., reports the case of a man operated upon for strabismus under cocaine, where six drops of a four per cent. solution had been instilled into each eye. After completion of the operation the patient complained of nausea and a feeling of faintness, the face became pale, the hands cold, and the skin covered with cold perspiration, pulse 48. All of these symptoms passed off in a few minutes. The next day cocaine was used as before, without unpleasant effects. The patient said the distress previously experienced was due to the knowledge he had that he was being cut, though he had no pain. He had fainted on a former occasion while witnessing an operation.

The enthusiasm of success on the one hand, and the suspicion of novelty on the other, are two factors which greatly influence us in our estimates as to the value of all new remedies. Should the former outweigh the latter, prominence is quickly gained. A preponderance of the latter delays proper appreciation and recognition. Occasionally, however, they counterbalance, and correct opinions are then quickly gained; but usually this process of vacillation continues to make belief uncertain, long after the question should have been definitely settled.

The unusual success which has been accorded to cocaine has given it impetus enough to override much that has been said against it—and I would fain call attention to such effects as the above, which have been ascribed to cocaine, and ask if the suspicions pointing to this agent as the cause have not been as premature as they are unjust.

Few operators in minor surgery have failed to observe the train of symptoms narrated above during operations without an anæsthetic. Nay, more, the sight of instruments or of blood, or the mere description of an operation, will at times bring on the various stages of fainting, which may culminate in the patient's falling senseless to the floor in a state of syncope. And in another class of individuals—nervous and excitable—such surroundings will bring on hysterical phenomena, simulating as strongly serious disorders as they are in themselves harmless. Having shown that it is not necessary to go so far as cocaine for an explanation of phenomena which have been observed during its use, it will be superfluous to state that physiological research has failed to reveal such properties as have been attributed to it upon the operating table. That cocaine can be used about the orbit with comparative impunity, it will suffice to say that three cases of enucleation which I am familiar with have been performed at the New York Eye and Ear Infirmary under its influence, the amount of the drug used being about 3 jss. of a four per cent. solution in each instance. Two of these cases occurred in the practice of Dr. D. C. Cocks, the other in my own, where the house surgeon, Dr. L. P. Walker, operated, and Dr. Walker informs me that he has a second case. No untoward symptom was noted in either of these four cases.

The importance of cocaine can hardly be over-estimated, yet it has its limitations; and not an unimportant one is the mental impressions which grow from a knowledge of what is going on during an operation performed under its influence. Local anæsthesia does not necessarily bring mental quietude and self-control, and if these two latter conditions are absent, the imagination is apt to play an important role in any operation undertaken. Whether a prominent feature or not, the imagination must always be considered in operations performed without a general anæsthetic.

25 East Thirty-first Street,
January 29, 1885.

A CASE OF TRAUMATIC TETANUS,

Occurring in the Service of the Late Dr. Johnson Eliot, Children's Hospital, Washington, D. C.

By LOUIS KOLIPINSKI, Pharm. D., M.D.,

resident physician.

On August 26, 1883, B—— O'D——, white, seven years of age, was admitted to the Surgical Ward of Children's Hospital. He had been brought from his home in Georgetown. His previous history, as obtained from his parents, was substantially as follows: Two weeks before, the child was kicked by a horse. He was carried home insensible and medical aid summoned. The wound was sewn up and cold-water dressings applied. No difficulty in mastication existed. On the Monday and Tuesday preceding his entering the hospital he was allowed to play about the house, in the open air. On the night of Tuesday he complained of a stiff and sore feeling about the neck and jaws. Wednesday these symptoms had increased, but food could still be taken readily. Thursday the trismus was marked, deglutition difficult, and mastication impossible. The next day general tetanus appeared. Toward evening, and on Saturday and Sunday, tetanic spasms were frequent. He complained of heat at the top of the head and pain in the region of the stomach. After the jaws had become closed he received hardly any food or medicine, both on account of the difficulty of swallowing and of insufficient nursing.

The examination showed that the wound had extended on the left side of the face from an inch to the outside of the angle of the mouth, upward and inward to the inner canthus of the eye. Below cicatrization was complete, above the edges were raw and glazed. An ectropion was forming on the inner half of the lower lid. On removing a scab which covered the orifices left by a suture, a small quantity of pus escaped. There was a bony projection over the malo-zygomatic articulation of the size of a hazel-nut; the molar prominence was gone; fracture of the superior maxillary bone was not determined. The face bore the sardonic expression. The eyes were brilliant, the pupils contracted. Perspiration about the neck and head abundant. The trismus was marked, the abdominal muscles firmly contracted. The temperature the first evening (fifth day of the disease) was 101.3° F.; the pulse 140. While being carried into the ward he had a general convulsion. Restlessness increased toward night, and constant watching was necessary to prevent him rolling from off the bed. At intervals he would scream and speak of pain in the epigastric region and at the nape of the neck. The occiput was buried in the pillows, and the child frequently cried, "Lift my head up!"

The spasms were of variable intensity. Some were slight, others so severe that cyanosis, stoppage of respiration, and a hardly perceptible pulse alarmed the attendants. Once were they accompanied with priapism and the spasmodic ejection of urine; twice with involuntary evacuation of the bowels. The rule that the upper extremities remain free was not observed. The arms and hands were tonically contracted. The body never rested on head and heels alone, although the back was strongly arched forward and justified the title of opisthotonic to the seizures. The spasms did not decline in violence with the progress of the disease. The last that occurred (thirty-fourth day) was as severe as any.

The exciting causes of spasm were noticed in a few instances. They were: Inserting the nozzle of the syr-

inge; gagging from attempts at swallowing milk; efforts at clearing away the tenacious mucus in the pharynx. It was attempted to obviate this last cause by the prone position. The child was easiest on his back. The lower extremities were not, or but seldom, drawn up.

Perspiration, as before mentioned, was most marked about the head and neck, and was more or less abundant throughout. Copious diaphoresis occurred on the twenty-second, twenty-third, twenty-fourth, and twenty-fifth days, with an abundant crop of sudamina. There was no difficulty in urination. The catheter was never required. The urine had the sp. gr. 1.015. Reaction acid; sugar and albumen absent. The bowels were never constipated.

At the meeting of the Consulting Board, on the sixth day, facial paralysis of the left side was observed. It is fair to suppose from the nature of the injury that this was due to an ascending neuritis, as explained by E. Rose. The pulse and temperature were noted morning and evening. The record shows no evening rise on the 8th, 9th, 11th, 12th, 13th, 14th, 15th, 16th, 19th, 21st, 26th, 27th, 28th, 29th, 30th, 31st, and 35th days. The pulse was more frequent in the evening on the 6th, 9th, 10th, 11th, 12th, 26th, 29th, 30th, 32d, and 33d days.

The increase in the number of convulsions on the tenth day was coincident with the reduction in the quantity of the remedies to one-half; the next day on again resorting to the original dose the spasms declined in number. Treatment was begun by washing out the rectum and injecting ten grains of chloral and thirty grains of potassium bromide. Two doses of two drops each of a fluid extract of Calabar bean were administered subcutaneously. Ether was used on one occasion to mitigate the severity of a spasm. Thereafter the following, by enema, was used throughout: Chloral, gr. xv.; potassium bromide, gr. xx.; fld. ext. Calabar bean, 2 to 3 drops, and whiskey, fl. ℥ j. The quantity of the last was subsequently diminished to half. Milk, beef-tea, and whiskey, by the bowel, followed each medicinal enema. In the intervals of relaxation, and when awaking from the sleep produced by the remedies, milk in considerable quantities (fl. ℥ viij.–xvj.) was swallowed. He was fed with a spoon, using his fingers to separate the lips. Deglutition was slow and fatiguing. The boy was placed in a dark room and kept there till recovery was complete. Sleep was continuous for from three to six hours; the spasms usually occurring on awaking. On the sixteenth day symptoms like those of acute alcoholic delirium appeared, and continued more or less until the thirty-fourth. Morphia, and, after two days, extract of hyoscyamus were used, as the chloral and potassium bromide had lost their hypnotic effect. Convalescence was very rapid, the appetite becoming voracious. On the twenty-ninth day a blister was applied along the spine. It produced very transient hæmaturia. On the 6th of October he was sent into the general ward.

Feeding Infants on Cow's Milk.—Dr. B. Bornn. of Dominica, W. I., adds his testimony in favor of the excellent results that may be obtained by feeding infants on cow's milk. Two children in his own family have recently thriven with unexceptionable vigor upon this mode of nourishment. His plan, for this and other cases, was as follows: A good native cow, which had calved about three weeks previous, was procured, and the milk obtained from her alone was used for the consumption of the little fellows. She was stabled and properly cared for, and fed on guinea grass. Some days she was allowed to graze. The same person milked her twice daily, and the tin vessel in which the milk was received was kept scrupulously clean. A plain six-ounce flask with an ordinary nipple was used and also kept scrupulously clean. The milk was boiled as soon as it was taken from the cow, and a little salt and sugar added.

Progress of Medical Science.

The Alkaline Treatment of Diabetes.—Dr. Minkowski (*Archiv. für Experimentelle Pathologie*), says that large quantities of oxybutyric acid are sometimes present in the urine of diabetics, and the two cases in which the presence of this substance has been carefully noted died of coma. He suggests that the cause of death was the loss of alkali from the organism, due to the presence of the large quantity of acid. Walter has shown that the introduction of acids into the blood of herbivora causes symptoms like those of diabetes, especially the peculiar dyspnœa, but the same result was not obtained in carnivora, or in a man. But he has tried the effect of giving alkalies in a case of diabetic coma, by introducing a large quantity of sodium carbonate by the mouth and rectum. Although the patient ultimately died, he recovered consciousness, and expressed himself better. The *post mortem* examination was negative. The results of Minkowski's researches give additional support to the alkaline treatment of diabetes, which has enjoyed much repute. Le Nobel, in a recent paper says, that acetic, formic, and sulpho-cyanogen compounds, all of which may occur in the urine, give a red coloration with ferric chloride, which disappears on acidulation, but not on heating. This last characteristic is the only means of distinguishing these compounds from aceto-acetic acid, so that after obtaining the color reaction, the effect of heat must be tried, and wherever the color does not disappear, the presence of aceto-acetic acid must be regarded as doubtful.

Tuberculosis of the Uterus.—Dr. W. J. Jones, of Baltimore, calls attention to this condition, which, though comparatively rare, yet has not received that attention from gynecological authors to which it is entitled. The clinical diagnosis can be based upon a persistent leucorrhœal discharge and other symptoms which would point to uterine troubles; and in any patient of a tuberculous tendency, in which these symptoms are present, we should be led strongly to suspect an involvement of the genital organs. The diagnosis is often aided by the expulsion of caseous masses from the uterus. The author evidently agrees with Koch, for he considers the discovery of the bacilli in the secretions a sure means of diagnosis. In the event of such a case found during life, before the secondary involvement of the surrounding tissues has taken place, a knowledge of how to treat it will present itself for consideration. The authorities which he has examined upon that part of the subject have little or nothing to say. Good hygienic surroundings, tonics, and good food, and perhaps the use of iodoform topically, might at least keep the disease at bay, and thus prolong the patient's life.—*Medical News*, January 3, 1885.

Stretching of the Lingual Nerve for Neuralgia.—Mr. Clement Lucas operated recently, for the relief of extreme neuralgia of the tongue, by stretching the lingual or gustatory nerve (*British Medical Journal*). He pointed out what he believed to be an original observation: that if the tongue be seized by the tip and drawn forcibly out of the mouth and on one side, the lingual nerve of the opposite side is made to stand out as a firm band beneath the mucous membrane on the side of the tongue, where it can be readily felt and secured. The operation was performed as follows: a suture was placed through the tongue to the right of the septum, by means of which the organ was drawn forcibly out and to the left side. A sharp-pointed hook was then passed under the nerve to fix it. The mucous membrane was then divided over the nerve for about half an inch, so that it could be readily seen, and an aneurism-needle having been passed immediately under the nerve, the sharp hook was withdrawn. The nerve was in this way easily reached and stretched.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 7, 1885.

STREET FILTH AND THE IMPENDING EPIDEMIC.

HEALTH authorities all unite in urging cleanliness as the great preventive measure against cholera. While we believe that the cholera germ propagates itself in the human subject quite independently of filth, and that its control and suppression depend upon other means and methods than those which insure cleanliness, we are not disposed to lessen the force of the appeal for municipal and domestic sanitary cleansing. On the contrary, we shall urge this great primal duty upon our authorities and citizens, with all the arguments at our command. There are sources of air-pollution in our midst which do not receive all the attention which they ought, and we propose to point them out from time to time, and fix the responsibility for their continuance where it belongs.

First, and most obviously, are our filthy streets. Street filth is the most perfect compound of animal, vegetable, and mineral decomposable matters yet devised, consisting in varying proportions of animal excrements, hairs, epithelial scales, etc., and the pulverized waste and wear of the pavements. These substances are reduced to an impalpable powder, which pervades the atmosphere and penetrates the deepest recesses of our dwellings.

Every housekeeper is greatly astonished at the all-pervading nature of city dust. She never fails to find it covering, however often cleaned, the furniture of the parlor, the bedroom, the library, the wardrobe, the kitchen, and dining-room. We speak advisedly when we state that the sickness and death-rate of New York is immensely augmented by street filth. This dust is the carrier to our houses, and to our throats and lungs, of the germs of diphtheria and other low forms of disease, which require only warmth, moisture, and a proper soil to propagate with the greatest virulence. Is the street-dust nuisance a necessity? We answer emphatically, No! The citizens submit to it because they have always done so. They do not know, for they have never seen, the appearance of a street in New York "well and thoroughly cleaned," as the law requires. They speak with admiration of the clean streets of Paris and London, but at home they are contented with the filth and foul air in which they were born and bred. The first step in setting our house in order for a pestilence should be the sanitary cleaning of the streets. By this we mean that the streets shall, as the law demands, "be well and thoroughly cleaned, and at all times kept clean."

The responsibility for filthy streets rests primarily upon the Commissioners of Street Cleaning, and secondarily, upon the Board of Health. It is the duty of the former "to well and thoroughly clean the streets, and keep them at all times clean," and of the latter, as the guardian of the public health, to see to it that they are in proper sanitary condition. We do not hesitate to say that both parties are culpably guilty of neglect of a great and pressing public duty.

We are only too well aware of the chronic and stereotyped response which will come from the Commissioner, and his apologists, to this indictment. First, we shall be told that the streets are cleaner than formerly, and, second, if they are to be made cleaner more money will be required. To the first assertion we reply, *the streets are not clean.* We are not to be cajoled with the assertion that the streets are cleaner than when the police did the work. We contend that they are not "*well and thoroughly cleaned, and at all times kept clean*" as the law requires, nor as the public health demands. In regard to the second we say advisedly, and emphatically, the Commissioner has ample funds at his command, nor is he hampered by any second party. The great wants in his department are brains and energy. There is evidently a fatal lack of these two requisites to success. We speak after no little experience and inquiry, when we assert that the streets of New York can be well and thoroughly cleaned, and at all times kept clean, with the proper and intelligent outlay of the million of dollars spent by the present Commissioner.

One thing is certain, even the present functionary might surprise us by "well and thoroughly" cleaning the streets once in a year, with his million. What a spectacle New York would present if its streets were so clean that everywhere the pavements could be seen? How delightful it would be to walk along our avenues on a breezy day, and not be suffocated by clouds of dust? But the serious aspect of the case appears when we reflect that we are liable to pass through a cholera epidemic with this vast surface of filth undisturbed, except by the winds and the dust machines, which are to drive it into our dwellings. It is idle to expect anything better from the present department. As we have stated, there is neither ability nor energy equal to the task in the organization. Look at the clumsy and worthless machinery and methods now employed.

Once in a week, or a month, the inhabitants of most of the streets are smothered by clouds of dust raised by a gang of superannuated sweepers, or by an apparatus mounted on wheels and singularly well adapted to stir up the impalpable powder on the surface of the street and diffuse it through their dwellings. On the following day no other trace of the work of this sweeping, or dust machine is noticeable than the universal coating of household furniture and clothing with street filth. Such a burlesque upon street cleaning, as we witness it in the other great capitals of the world, is unpardonable, and should not be tolerated while an epidemic is staring us in the face. Meantime we hear no protest from the Board of Health against street filth, though the streets about headquarters are strikingly illustrative of the truth of the statements which we have made. Long familiarity with filth certainly begets indifference to its

existence, and it is to this cause we must ascribe the apathy of this body to one of the most patent nuisances in the city. It is probable that the only effectual method of bringing both our health and street cleaning officials to a sense of their duty is to summon them before the Grand Jury.

News of the Week.

The New York Orthopædic Society.—The first annual meeting of the recently organized Orthopædic Society was held on the evening of January 29th. There was a very good attendance of orthopædic and general surgeons, and much interest was manifested in the discussion of Dr. Judson's paper on "The Management of the Abscesses of Hip Disease." The following officers were elected to serve for the ensuing year: Dr. V. P. Gibney, President; Dr. A. B. Judson, Vice-President; Dr. T. L. Stedman, Secretary; Dr. W. T. Bull, Treasurer.

A National Bureau of Public Health.—There has been introduced in the United States Senate a bill providing for the creation under the Treasury Department of a Bureau of Public Health. The bill states that the chief officer of the Bureau shall be denominated the Commissioner of Public Health, and shall be under the general supervision of the Secretary of the Treasury. He shall be appointed by the President, by and with the advice and consent of the Senate, and shall hold his office for the term of five years, unless sooner removed by the President, upon reasons to be communicated by him to the Senate, and until his successor shall be appointed and confirmed. The Commissioner in question is to appoint seven Sanitary Superintendents and a Public Analyst.

The National Board of Health.—The report of the National Board of Health for 1884 was transmitted to Congress on February 2d. The report gives an outline of the movements of the several epidemics of Asiatic cholera which occurred in this country in 1832, 1849, 1854, 1866, and 1873, and calls particular attention to the dangers to which the country is exposed by the recent prevalence of the disease in Western Europe. The report says further, that in the absence of specific appropriations all investigations have been suspended and an appropriation of $43,000 is asked for such work. In addition to this it is earnestly recommended that an appropriation of $500,000 be made, to be expended in aid of State and local Boards of Health in preventing the introduction and spread of contagious or infectious diseases.

Dr. Gaillard.—We learn with profound regret of the death of Dr. Edwin Samuel Gaillard, the veteran medical journalist and editor, which occurred at his home in Ocean Beach, N. J., on February 2, 1885. Dr. Gaillard was born near Charleston, S. C., January 16, 1827. He was graduated from the University of South Carolina, at Columbia, in December, 1845, and from the South Carolina Medical College, at Charleston, with first honors, in March, 1854. In June of the same year he moved to Florida and took charge at once of a large practice, being made a member of the State Medical Society. Three years later he removed to New York, and after a few months' residence here he went abroad and remained for a year. In 1861 Dr. Gaillard joined the Confederate Army at Richmond, and he followed the fortunes of the South until the war closed. At the close of the war Dr. Gaillard practised his profession in Richmond for three years, afterward moving to Louisville, Ky. In 1861 Dr. Gaillard received the Fiske Fund prize, and in 1865 the prize of the Georgia Medical Association. A year later he founded the *Richmond Medical Journal*, which he moved to Louisville in 1868, publishing it under the title of the *Richmond and Louisville Medical Journal*. In 1874 he established the *American Medical Weekly*, having the year previously received from the University of North Carolina the degrees of A.M. and LL.D. A few years ago he removed his journal and residence to this city, where he published *Gaillard's Medical Journal*. Dr. Gaillard was a member of the various Louisville medical societies, was a correspondent of the Gynecological Society of Boston, the Louisville Obstetrical Society, an honorary member of the South Carolina Medical Association, and an honorary and corresponding member of the College of Physicians and Surgeons of Arkansas. Dr. Gaillard was elected President of the Richmond Academy of Medicine in 1867, President of the Medico-Chirurgical Society in 1868, and President of the American Mutual Benefit Association of Physicians in 1875. He was made Dean of the Louisville Medical College at its organization, and was also Dean of the Kentucky School of Medicine. Dr. Gaillard was twice married; first to a daughter of the Rev. Edward Thomas, of Charleston, who died leaving no children, and afterward, in 1865, to a daughter of Prof. C. B. Gibson, of the University of Maryland.

Adulterated Quinine.—Dr. Edson, of the Health Department, has been buying quinine at forty or fifty drug stores, and the chemist of the Sanitary Bureau has discovered adulteration in many of the samples thus obtained. In some cases fifty per cent. of the compound alleged to be pure quinine was made up of worthless stuff.

Dr. Burbank, United States Navy, died suddenly on January 31st, at Portsmouth, N. H., of heart disease.

In the Discharge of Duty.—Dr. Samuel W. Smith, Sanitary Inspector, New York City Board of Health, in charge of the pest-house, 557 West Thirty-second Street, caught typhus fever last week, and has been removed to Riverside Hospital.

Dr. Hans Powell, a veteran army surgeon, and a prominent member of the Grand Army of the Republic, died at his home in this city on January 24th. He was born in Dublin, Ireland, in 1842, and received his diploma from the College of Surgeons in that city in 1860.

The Medical Association of Georgia does not appear to have deeply intertwined itself into the life and thoughts of the Georgia doctors. Says the *Atlanta Medical and Surgical Journal*: "There are over two thousand physicians in Georgia to-day; a vast majority of that number could not tell you, if asked, whether there positively was a State Association or not, and fewer still could tell you who the President of the Association was and when the annual meetings were held."

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Seventy-ninth Annual Meeting, held in Albany, N. Y., February 3, 4, and 5, 1885.

FIRST DAY—TUESDAY, FEBRUARY 3D—MORNING SESSION.

THE Society convened at Geological Hall, and was called to order at ten o'clock by the President, DR. B. F. SHERMAN, of Ogdensburg.

Prayer was offered by REV. DR. J. LIVINGSTON REESE.

THE PRESIDENT read his inaugural address, at the close of which he appointed the following

COMMITTEES.

Business Committee.—Drs. J. V. Kendall, of Baldwinsville; Laurence Johnson, of New York; and L. E. Felton, of Potsdam.

Committee on Credentials.—Drs. Eugene Beach, of Gloversville; C. E. Willard, of Catskill; and L. M. Bennett, of Watkins.

INAUGURAL ADDRESS.

GENTLEMEN: In behalf of the Medical Society of the State of New York I welcome you to this, its seventy-ninth annual session.

I recognize before me many familiar faces, also some new ones, and am sorry to see that some of our former friends and co-workers are *conspicuous* by their absence; but earnestly hope and believe that, after a sober second thought, our brothers will return to the old home, the doors of which shall always be open to receive all true honest workers in science and searchers for the truth, however much we may differ in the matter of ethics.

I am not unmindful of the high honor conferred upon the presiding officer of this Society, nor of the responsibilities accompanying it. For the former I most sincerely thank you; for the latter I earnestly ask your forbearance and support, without which I shall be wholly inadequate to the duties before me. I have few suggestions to make, and little to say that will interest you.

The steady march of our honored profession toward the positive and real in science is marked, and in no place more so than in our own State. We live in an age of wonderful improvements, and our profession in all its branches has kept fully abreast with the age. One of its latest gifts to suffering humanity is the new anæsthetic, cocaine, which promises, in its relief of pain and suffering, to be second only to ether and chloroform, and to simplify many important as well as minor surgical operations. To make this (the largest and one of the oldest medical societies) what it should be, demands an earnest effort on the part of us all, and perhaps some change of programme.

We should have a better room in which to hold our meetings; one with more perfect acoustic properties as well as better ventilation, thereby enabling the audience to hear the speaker, and to remain quiet, during the several sessions.

As we represent a large constituency, and pay a fair proportion of the taxes, it is but just that we should have the use of a suitable room in the new Capitol, for one week in the year, in which to hold our meetings, and I advise measures to be taken to that end.

Too many members and delegates come here to serve two masters: to represent their county societies in this meeting, and at the same time to represent their local Masonic lodge, in the annual Masonic convention, or to see and study the white elephants of the city. The result is, they come into this meeting at unusual hours, in the middle of an interesting paper, or its discussion, which of necessity they do not understand, and soon leave with a mutter that "this is not a very interesting meeting," receiving no benefit themselves, and only disturbing others.

This is only to be corrected by every member and delegate feeling that *he* is a part of the Medical Society of the State of New York, and that this is *his* meeting, and *he* is responsible for the work done in it; for those of us who do not feel equal to preparing a scientific paper, can listen respectfully, and to advantage, to the reading of those presented by others; which, though a humble, is a very important, part of such gatherings.

Gentlemen who come here with carefully prepared papers, want at least a reasonable time in which to read them intelligibly, and not be obliged to crowd into five minutes what requires twenty; and then the members and delegates should be prepared and have plenty of time to discuss the same.

To do this we must have fewer papers or more time. The time can be lengthened by prolonging our sessions another day, or can be more effectively utilized by organizing sections, and devoting the afternoons to work in them.

That the discussions may be thorough, it is desirable that the title of the papers to be read, be in the hands of every member and delegate some weeks before the meeting.

There is no reason why the presiding officer should be taxed with the labor and responsibility of this printing and correspondence. I therefore advise that it be made the duty of the Secretary to issue these circulars, the expense of which to be paid by the Treasurer, with additional pay to the Secretary, who is now poorly paid for his services.

The coming International Medical Congress, to be held in Washington in 1887, should receive especial attention at this meeting, and measures taken to place this Society in the proper attitude to throw the weight of its influence in its favor, and to be properly represented.

A communication has been received from our elder sister, the Medical Society of New Jersey, which I herewith transmit to you. The importance of the subject, and courtesy to our sister society, demand that it receive attention at this meeting. The subject is a prescribed preparatory curriculum for all medical students, and is one of so much moment that the action of this Society should be taken advisedly. I therefore suggest that it be referred to a special committee, to report at our next annual meeting. We should once more memorialize Congress to furnish a fire-proof building for the preservation of the medical library and museum.

It must have been observed that the attendance upon, and interest in, the reading of the President's annual address, has yearly diminished. Even last year, when every one knew we were to have a scholarly and eloquent address, the attendance was small. In my opinion the time of the Society will generally be more profitably spent in scientific work. I therefore advise the amendment of Article II., Section 2, of the by-laws, in a way to receive but one address from the President, and that at the opening of the first day's session.

If my suggestions as to the duties of the Secretary are adopted, Section 4 of Article II. will also require amendment.

It is earnestly desired by your presiding officer, that whatever questions or debates may come before this Society during its several sessions, may be conducted by all parties in a spirit of candor and forbearance, due to all honest difference of opinion; remembering that the same object is sought by all—the elevation of the character and standing of the profession; and that the minority will not forget the first duty of all good citizens, to yield cheerfully to the opinion of the majority.

Since our last meeting some of our number have been taken from us by death, and while all are honorable and deeply mourned by us, two of the most eminent teachers and landmarks of the age have been taken—men whose

places it will be hard to fill—Willard Parker, of New York, and Samuel D. Gross, of Philadelphia.

On motion by Dr. Potter, of Buffalo, the President's address was referred to a committee of three, subsequently appointed and consisting of Drs. Potter, Squires, of Elmira, and Phelps, of Chateaugay.

COMMUNICATIONS FROM COUNTY MEDICAL SOCIETIES.

A communication from Erie County, approving of the establishing of a Board of State Medical Examiners, composed of men having no connection with any medical school, was received and ordered placed on file.

BIOGRAPHICAL SKETCHES.

Dr. Wesley M. Carpenter, of New York, presented biographical sketches of James R. Wood, M.D., LL.D., by Frederick S. Dennis, M.D.; of Willard Parker, M.D., LL.D., by William H. Draper, M.D.; of John Glover Adams, M.D., by Gouverneur M. Smith, M.D.; of Joel Foster, M.D., by Francis V. White, M.D.; all of which were referred to the Business Committee, and subsequently recommended for publication.

Dr. Carpenter also presented amendments which had been adopted by the Medical Society of the County of New York, which were referred to the Committee on By-laws; also the following resolution, which was referred to the same committee:

"*Resolved*, That any member neglecting to pay dues and assessments for two years shall forfeit his or her membership, provided he or she shall have received from the *Treasurer* one month's notice of his or her delinquency. Such member may be reinstated, upon the recommendation of the *Comitia Minora*, by the payment of his or her arrears."

He further presented the following communication from the *Comitia Minora* of the Medical Society of the County of New York:

"1. Are all practitioners of medicine required by the laws of this State to become members of some County Medical Society?

"2. How can membership in a County Medical Society be terminated?

"3. If membership can be terminated by resignation, must the resignation of a member be accepted by the Society in order to make it operative?"

A resolution from the Medical Society of the State of Nebraska, concerning

FOREIGN CORRESPONDENTS,

was read and referred to a special committee, composed of Drs. A. Jacobi, of New York, W. S. Ely, of Rochester, and W. H. Bailey, of Albany.

Dr. S. B. Ward, of Albany, of the Committee of Arrangements, introduced Dr. H. I. Bowditch, of Boston, honorary member, and the President invited him to a seat on the platform.

The President appointed Dr. W. H. Bailey, of Albany, to fill a vacancy on the Committee of Arrangements.

MEMBERS BY INVITATION.

Dr. S. B. Ward, of Albany, Chairman of the Committee on Arrangements, reported the following names: R. A. Witthaus, of Buffalo; John Gerni, of Auburn; S. A. Russell, E. A. Bartlett, John B. Stonehouse, N. B. La Moore, and W. G. Tucker, of Albany.

Dr. W. W. Potter, of Buffalo, then read a paper on

PELVIC ABSCESS,

in which he reported an acute case with remarks: Mrs. B——, aged thirty-eight, twice married, the mother of three children by first marriage. The prominent symptoms were nausea, vomiting, pain, pulse 100 to 120, increasing swelling detected by vaginal examination, chills, rigors, sense of fluctuation, etc. Aspiration was performed, and three pints of pus removed, the needle being introduced through the vaginal vault in the median line. A drainage-tube was inserted, the cavity washed out with a mercuric solution, the washing repeated several times a day afterward, first with the mercuric solution, 1 to 3,000, afterward with carbolic acid solution, and subsequently the cavity was injected with an emulsion of iodoform and starch. The following were regarded as the interesting features of the case: (1) rapidity with which such a large abscess formed in the non-pregnant state; (2) the corresponding rapidity with which it filled by granulation; (3) enormous quantity of pus evacuated at first; (4) injections of iodoform followed by such beneficial results. These points were discussed by the author of the paper until his allotted time expired.

Dr. Wylie, of New York, thought the abscess in this case was due to one of two causes: (1) hematocele; (2) septic material carried into the pelvic cavity through a salpingitis. He also thought the rapid recovery was due to the fact that only one suppurative cavity existed. The solution of the mercuric bichloride, 1 to 3,000, he regarded as too strong to be used as frequently as it should be where the fetor is great; the washing, instead of being once or twice a day, should be constantly, of the strength of from 1 to 5,000 to 1 to 10,000. Dr. Wylie preferred the method of treatment by abdominal section.

Dr. Ely, of Rochester, reported a case of "latent pelvic abscess," occurring in an unmarried girl, sixteen years of age. As there was no pointing, in accordance with consultation with Dr. E. M. Moore, a large trocar was introduced below the navel and brought out through Douglas' cul-de-sac, and three pints of pus were removed. Through the canula a drainage-tube was inserted, frequent washings practised, with simple warm water, and the patient recovered rapidly. The thorough drainage was the feature especially interesting in the case.

Dr. H. I. Bowditch, honorary member, of Boston, referred to a case of abscess occurring in a child two years old. It was treated by puncture of the abdomen and removal of a large quantity of pus. Pus reaccumulated, and then was done what Dr. Bowditch believed should not be shrunken from, as was generally the case—namely, the abdomen was opened and the cavity washed out thoroughly. He thought that the profession was as much afraid of opening the abdominal now as it was, thirty years ago, of opening the pleural cavity, an operation which, at present, is one of the most frequently performed by surgeons.

Dr. Baker, of Lockport, spoke of the use of continuous hot-water vaginal injections, suggested by Dr. Emmet, of New York, with the view of aborting the abscess.

Dr. Potter, in closing the discussion, remarked that most of the points brought out in the discussion had been considered in the unread portion of his paper.

Dr. David Webster, of New York, read a paper on

JEQUIRITY AS A REMEDY IN GRANULATED LIDS,

in which he spoke of the beneficial effects produced by the drug, but said it should be used only in cases in which considerable pannus existed, in solution not stronger than one-fourth of one per cent., making the application only once a day, and not repeating it after the characteristic inflammatory reaction began to show itself.

Dr. Roosa, of New York, spoke of the benefit following the guarded use of the remedy; and Dr. Pooley, of New York, spoke emphatically of the dangerous action of the drug; and Dr. Knapp, of New York, believed that the circle of the use of the jequirity solution was so restricted that it could be legitimately employed only in a very few cases.

Dr. Webster, in closing the discussion, thought the remedy should not be discarded because it was capable of doing damage, but that it should have a place in ocular therapeutics.

Dr. Daniel Lewis, of New York, read the

REPORT OF THE COMMITTEE ON LEGISLATION,

which mentioned the work done by the Committee in the way of checking obnoxious medical legislation, and

recommended that an act to the present law be introduced into the Legislature, asking for an amendment which would permit County Medical Societies to hold property not to exceed $50,000, and further providing that no member shall be assessed a sum greater than *five* dollars in any one year. The recommendation of the Committee was amended, making an exception of the County of New York, so that its medical society might be permitted to hold property to the amount of $100,000, and then adopted.

Dr. H. G. Piffard, of New York, from the Special Committee appointed at the last annual meeting to prepare a bill establishing

A STATE BOARD OF MEDICAL EXAMINERS,

read the proposed Act, which was ordered printed and made the special order for the evening session; Drs. Hopkins and Vanderveer dissenting to the report.

Dr. J. G. Curtis, of New York, from the

COMMITTEE ON EXPERIMENTAL MEDICINE,

reported that no bill had been introduced into the Legislature by the anti-vivisectionists during the last year, and also offered a resolution reaffirming the Society's adherence to the belief that experimentation on animals was essential to progress in medicine. Adopted.

Dr. E. V. Stoddard, of Rochester, Chairman of the

COMMITTEE ON HYGIENE,

read the annual report, which was accepted and ordered placed on file.

Dr. W. W. Potter, of Buffalo, Chairman of the

COMMITTEE ON PRIZE ESSAYS,

reported that no essay had been presented during the past year.

Dr. D. B. St. John Roosa, of New York, then read a paper on

THE REMOVAL OF THE CATARACTOUS CRYSTALLINE LENS IN ITS CAPSULE.

The removal of the crystalline lens in its capsule for the cure of cataract, as is well known by this learned body, is by no means a new operation. It is a favorite method of at least one of the distinguished ophthalmic surgeons of our time (Pagenstecher). If it can be safely performed, I think it perhaps offers the best means of curing senile cataract. When the lens is removed with its capsule, one of the evil consequences that frequently follows even a successful operation, when the envelope of the lens is divided with an instrument, is generally avoided. Of course I mean the formation of a web-like or thick neoplastic membrane. This membrane is frequently such an obstruction to vision that the patient requires a subsequent operation, not entirely without danger to the eye; and until this operation is performed, the patient is deprived of much of the benefit that comes from the removal of the lens. Indeed, in some cases the capsule which is left behind is situated in such a portion of the pupillary space, that even when no serious inflammation occurs, it of itself may prove a formidable obstruction to the entrance of rays of light. Much surgical ingenuity has been expended in performing such a division of the capsule as will cause it to roll out of the way. I am also aware that it has been lately taught that the operation for extraction of cataract should really be divided into two parts: first, the removal of the lens, and second, after the interval of a few weeks or months, upon the web of tissue formed by the cataract and the inflammatory process. The operation for cataract, when a secondary procedure must certainly follow it, however successful, becomes a long drawn out affair. This is especially intolerable for old persons, who have already waited through months or years of gradually failing vision for their cataract to be ripe.

An operation that will, in a given number of cases, sensibly diminish the proportion of those in which a secondary operation is required, will, I think, be a great boon to those who are blind from opacity of the crystalline lens. If, however, the operation for the removal of the lens in its capsule be so difficult a performance and dangerous, that the proportion of total losses of sight are increased, these things should weigh very heavily in the scale against it. For I doubt not that it is better that ninety patients out of a hundred should secure vision enough to go about alone, and to help themselves in the ordinary requirements of life, than that seventy-five should be able to read and write the finest characters, while the other twenty-five become totally blind. It seems to me that the operations for removal of the lens in its capsule that have been thus far proposed, have required so much more instrumental handling of the eye than is necessary in the ordinary operations, as to make them too dangerous for general adoption. The removal of the lens as a whole, in the operations that have thus far been proposed, is usually, if not always, accomplished by an instrument introduced *into* the eye.

Another defect in these operations, as it seems to me, is that it is accompanied by the operation for cutting off the iris. Now, if we can find an operation that will safely remove the lens in its capsule, without the introduction of an instrument into the eye, either to cut off a piece of the iris, or to scoop out the lens, I think we shall make an advance in ophthalmic surgery. I have performed in twenty-four cases what I think may be such an operation. I am not ready to claim that it is a substitute for the other methods in all cases of senile cataract, but I think in quite a large proportion it is a better operation than has yet been proposed. My method of removing the lens in its capsule is as follows:

First.—After inserting the speculum and holding the eye in the usual way with the fixation forceps, using a Graefe cataract knife, I make a large flap of the cornea, if possible, one involving one-half of its circumference, and entirely in that tissue. After transfixion, and when the section is about half completed, the back of the knife is deliberately turned so as to rest almost vertically upon the iris and crystalline lens, and some pressure is made with a view of rupturing the zonula, and dislocating the lens. The section is then finished.

Second.—The lens is then pressed out of the opening by pressing upon the lower lip of the wound, and upon the cornea, the lens being followed up in the usual manner. The pressure is made by two india-rubber spoons, used, of course, at the same time. I think the dread of too great pressure upon the cornea for the purpose of forcing out the lens is unduly great in the minds of those who have been accustomed to accompany all their operations for cataract with an iridectomy. Since I have begun to perform this operation, I have failed in a few instances to remove the lens without first dividing the capsule. That is to say, I have found that the pressure to be exerted was too great to admit of its being continued without pushing out at the same time the vitreous humor. I think that this was generally due to the fact that the corneal incision was too small. In a few others I have also been obliged to add to the operative division of the capsule an iridectomy. But of late, that is, since the first of October, I have not failed in any case to remove the lens in its capsule by the method described, when I have set out to do so. While writing this article, I have two patients in the Manhattan Eye and Ear Hospital, who have been within the last ten days successfully operated upon by this method. I think the use of cocaine, as a local anæsthetic, has assisted considerably in the successful performance of my operations. I do not now think that it is as dangerous an operation as the ordinary one. The vitreous humor is not so apt to escape as when the capsule is divided, and an iridectomy performed. To my mind the operation of iridectomy, to assist in the removal of a cataract, is a detraction from that which without it is a singularly brilliant surgical exploit.

It is generally claimed that it is of importance in assist-

ing the safe removal of the lens, and that it decreases the dangers of subsequent inflammation.

To say that the cutting off of a tissue so vascular, so richly supplied with nerves, and having such a perfect muscular system, is less dangerous than a moderate and momentary pressure by the lens upon its yielding structure, is to say something that has generally been accepted as true, but nevertheless I am disposed to question its correctness. I am persuaded that a return to the old method of operating when the iris was not cut, whether the capsule be divided by an instrument or not, would be a gain for ophthalmic surgery. If to this we may add, as I now think we can, a safe means of extracting the lens in its capsule, the best that we can hope for in the cure of cataract by operation will have been accomplished.

As is well known by the profession, it has been held, and I believe with good reason, that the removal of immature cataracts is attended with more danger to the eye than that of fully opaque ones. If my operation for removal of the lens in its capsule can be generally performed with success, the number of persons who can be relieved of impairment of vision will be somewhat increased, because unripe cataracts, and those going on to maturity very slowly, may be as safely removed as those that are completely opaque. Another advantage which may be claimed for this method is that the number of instruments introduced into the eye is cut down from the forceps, cystotome, and knife, to the knife alone.

The paper was discussed by Dr. Knapp, of New York; Dr. Webster, of New York; and Dr. Bendell, of Albany, and the discussion was closed by Dr. Roosa.

The following papers were

READ BY TITLE:

"Obituary Sketch of Dr. Coates, of Batavia," by Dr. W. W. Potter, of Buffalo; "Limitations in the Use of Cocaine," by Dr. C. R. Agnew, of New York.

The Society then adjourned to meet at 3 P.M.

AFTERNOON SESSION.

The Society was called to order at 3 P.M., by the President.

COMMITTEE OF NOMINATION.

The following were reported as the persons elected for the Committee of Nomination, by the meetings of the several Senatorial districts: *First District*—S. O. VanderPoel, of New York; *Second District*—E. F. Brush, of Westchester County; *Third District*—Herman Bendell, of Albany County; *Fourth District*—E. Beach, of Fulton County; *Fifth District*—I. N. Goff, of Madison County; *Sixth District*—I. C. Edson, of Broome County; *Seventh District*—F. M. Hamlin, of Cayuga County; *Eighth District*—F. J. Baker, of Niagara County; *Member appointed by the President*, Dr. W. W. Potter, of Buffalo.

DR. M. JOSIAH ROBERTS, of New York, read a paper on

ANATOMICAL GEOMETRY AND TOPONOMY: AN INTRODUCTION TO THE SCIENTIFIC STUDY OF DEFORMITIES.

The chief object was to demonstrate the range of normal articular mobility; this being established, the pathological deviations could be determined with a degree of accuracy which was susceptible of expression by mathematical formulæ. Descriptions of instruments of precision were then given, as the articular goniometer, the adjustable protractor, and the epiphedometer.

The paper was discussed by Dr. A. M. Phelps, of Chateaugay.

THE PRESIDENT, at the suggestion of Dr. William C. Wey, of Elmira, Chairman of the Committee on By-Laws, who was unable to attend the meeting, appointed

A TEMPORARY COMMITTEE ON BY-LAWS,

consisting of DR. H. G. PIFFARD, of New York, Chairman, and DR. W. S. ELY, of Rochester, in the place of DR. A. HUTCHINS, of Brooklyn, also absent. These gentlemen were to serve as committeemen with the Secretary, Dr. Wm. Manlius Smith, of Syracuse.

DR. T. H. POOLEY, of New York, then read a paper entitled

SOME OBSERVATIONS ON THE USE OF HYDROCHLORATE OF COCAINE,

with special reference to its local anæsthetic influence and its effect as a therapeutic agent in ophthalmic surgery. The methods employed had been instillations and injections into the lachrymal sac and duct.

To facilitate the examination of the eye and the treatment of its affections, it had certain advantages over atropine, but as a local anæsthetic, to precede the application of caustics, he had thus far not been pleased with the results. It had occurred to him that the drug might relieve the pain of acute glaucoma, although he had not tried it in this affection.

In conclusion Dr. Pooley referred to two observations recently made by Weber: (1) the production of a sensation of cold; (2) augmentation of the power of the external recti muscles; facts which may influence the therapeutic use of this drug.

The paper was discussed by DR. H. KNAPP, of New York, who referred first to the discovery of the anæsthetic effect of the alkali, and second, of the mode in which it produces its peculiar influence; the latter was accomplished through the agency of the sympathetic nervous system. There were no dilator fibres in the human iris, and whatever dilatation was caused was done through the blood-vessels acted upon by the sympathetic nerves. Dr. Mittendorf had pointed out that action was accomplished through the sensory nerves, but Dr. Knapp was not quite prepared to accept that view, although it seemed quite probable that both sets of nerves were affected by the alkali. It has no bad effect on the healing of wounds.

DR. DAVID WEBSTER, of New York, spoke of a case of acute glaucoma in which, at Dr. Agnew's suggestion, cocaine was used, and without effect. With regard to the effect on inflamed eyes, the anæsthesia was not so readily produced as under other circumstances. Concerning iridectomy, he had about made up his mind not to perform any more operations in cases in which the lens was transparent, because of the liability to injure the capsule and thus produce a traumatic cataract.

DR. SHERWELL, of Brooklyn, referred to a case of papilloma of the larynx, minor operations in the pharynx, and dilatation of anus for subsequent operation on a fissure. In all it was unsuccessful, except in producing anæsthesia of the mucous membrane of the pharynx.

The Chairman of the Committee of Arrangements introduced DR. F. K. PADDOCK, of Pittsfield, Mass., delegate from the Massachusetts Medical Society, who also spoke of the use of cocaine.

DR. POOLEY closed the discussion, in which he spoke of the impropriety of attempting to perform capital operations without the aid of general anæsthesia.

The Chairman of the Committee of Arrangements reported the following

MEMBERS BY INVITATION:

Drs. Robert Babcock, G. A. Bradbury, F. L. Classen, S. R. Morrow, John Thompson, Lorenzo Hale, O. D. Ball, P. J. Keegan, Martin J. Dwyer, D. Fleischman, J. D. Craig, T. P. Bailey, George Munson, J. M. Bigelow, Geo. E. Lyon, West Troy, W. C. Phillips and C. E. Bruce, of New York, G. A. Collamer, Toledo, O., and J. E. Winters, New York.

DR. WALLIAN, of Bloomingdale, then read a paper on

DIOXIDE OF HYDROGEN,

in which was shown its powers as a disinfectant and antiseptic, in a large variety of affections; in liquid solution of twelve volumes. It is a remedy which has too long been in obscurity. The paper was referred to the Committee on Publication.

Dr. W. S. Ely, of Rochester, then read

AN ABSTRACT OF A CASE OF CANCER OF THE LIVER, CHARACTERIZED BY A SERIES OF LOW TEMPERATURES.

Mrs. L. R——, aged sixty-two years, who gradually developed a cachexia with emaciation, attended by vague abdominal pain, loss of appetite, etc., and death. The case was interesting especially with reference to temperature. Six hundred and forty-nine observations were made, and four hundred and sixty showed temperature below normal. The highest was 104° F.; the lowest 91° F., on the one hundred and eighty-first day.

On the one hundred and ninety-sixth day the temperature was 91.5° F. The pulse bore no relation to the fluctuations of temperature. There was no evidence of collapse at any time, nor any chill, notwithstanding the low degree reached, which had been said, by some authorities, to be invariably fatal. The thermometer was used in the mouth in making these observations, and with all precautions to eliminate any possible error.

Dr. Hopkins, of Buffalo, asked concerning the quantity of urine passed and also food taken.

Dr. Ely replied that the urine was frequently below the average, but was negative, practically, on chemical examination, and the food consisted of broths, milk, and eggs.

Dr. Stoddard, of Rochester, directed attention to sub-normal temperature in chronic disease occurring as frequently as higher range in more acute disorders.

Dr. T. H. Squires, of Elmira, reported

A CASE OF TUBAL PREGNANCY,

in which rupture occurred. A large quantity of blood was removed by aspiration through the abdominal walls, followed by discharge through the vaginal wall from an opening made by a bistoury, also from the rectum, and the patient apparently nearly recovered, when unfavorable symptoms developed when abdominal section was performed, with the result of finding general adhesions which rendered the completion of the operation impossible; the wound was closed, and the patient again nearly recovered. but symptoms of blood-poisoning developed, and the patient died *nine* months and *four* days after the rupture of the fœtal sac. The case emphasized the importance of early diagnosis, so that those remedies, such as electricity, might be used for destroying the life of the embryo, which had been recently so successfully employed.

In the course of this case the patient's temperature was several times as low as 95° F., and, for a long time, was sub-normal one or two degrees.

Dr. L. E. Holt, of New York, read a paper entitled

DOES QUININE ABORT PNEUMONIA?

The author of the paper thought it was impossible to abort pneumonia with quinine, basing his conclusion upon observations made on children. Whether the same was true of adults he was not prepared to say. He explained the cases of apparent abortion of pneumonia on the ground that there was a malarial complication.

Dr. A. N. Bell, of New York, was sure that he had observed zymotic pneumonia; that is, pneumonia occurring with and influenced by what was considered ordinarily as malarial poisoning.

Dr. A. L. Loomis, of New York, referred to the relations which passive and active pulmonary hyperæmia sustained to pneumonia. He believed that the two conditions were decidedly different, and that, in children especially, passive hyperæmia might give rise to physical signs such as lead to the belief that there exists partial consolidation of the lung; whereas in active hyperæmia the physical signs are those of fluid in the bronchial tubes, perhaps a condition of beginning inflammation.

He did not believe that the passive result from malarial infection was likely to develop into pneumonia, unless there was something added to it.

He believed that acute lobar pneumonia was an infectious disease when it first strikes its blow; it will then pursue a certain course, and it was impossible to arrest it.

Again, there was a growing tendency, that there was a difference between the pneumonia of the present day and that met with ten or fifteen years ago. It seemed to him that all diseases met with at the present day were different from those which occurred ten or fifteen years ago. For example, diphtheria and cerebro-spinal meningitis, this number of years ago, were not common, and pneumonia was not regarded as a specially dangerous disease; but now these diseases were prevalent both in cities and in the country, and pneumonia seems to be taking on something of the same type; it is a different disease, and he did not believe that it was possible to avert pneumonia when once it had struck its blow.

The discussion was continued by Dr. Wallian, and by Dr. Starr, of Rochester.

The Society then adjourned to meet at 8 P.M.

Evening Session.

The Society was called to order at eight o'clock by the President, and the special order was taken up.

AN ACT TO ESTABLISH A BOARD OF MEDICAL EXAMINERS OF THE STATE OF NEW YORK.

Dr. Lewis, of New York, read the first section, and it was discussed with reference to the propriety of having one or two boards; Drs. Hopkins, of Buffalo, Vanderveer, of Albany, Roosa, of New York, Ely, of Rochester, Sturgis, of New York, opposing the establishing of two Boards of Examiners; Lewis, Knapp, Piffard, J. G. Curtis, and Jacobi, of New York favoring the same. The discussion also included the reasons why no provision had been made for examinations in anatomy, physiology, and chemistry, and this explained why six instead of nine members were named.

The first vote was on the question of recommending that there be two boards. Affirmative, 25; negative, 43. The vote was then taken on the question of six. Affirmative, 20; negative, 39.

The second section was read, and subjected to several amendments, chiefly with reference to the appointing power and to the duration of the Board, whether or not it should be elected annually.

The amendment offered by Dr. Kendall, of Baldwinsville, which proposed to substitute the Board of Regents for the Governor, was carried.

The amendment made by Dr. Ely, of Rochester, that the Board of Regents should appoint from nominations made by the three incorporated medical societies of the State, having been lost,

Dr. Jacobi, of New York, moved to reconsider the vote by which the Society directed that the bill be read by sections. Carried.

Dr. Piffard moved to reconsider all action taken on the bill. Affirmative, 52; negative, 4.

A motion to adjourn was lost.

Dr. Jacobi moved the adoption of the bill now before the Legislature, and read the same, which places the formation of the Board in the hands of the Regents of the University of the State, and the three incorporated medical societies of the State.

Dr. Vander Poel, of New York, moved that the bill be printed and made a special order for Wednesday afternoon, at three o'clock. Affirmative, 38; negative, 19.

The Society then adjourned to meet Wednesday morning.

Second Day—Wednesday, February 4th—Morning Session.

The Society was called to order at ten o'clock by the President, and prayer was offered by Alfred C. Post, M.D., LL.D., of New York.

Dr. Ward reported Drs. W. O. Stillman, B. U. Steenberg, and M. J. Lewi, of Albany, as

MEMBERS BY INVITATION.

Dr. C. H. Porter, of Albany, then read the annual

REPORT OF THE TREASURER,

which showed a balance in the treasury of $380.37. The report was accepted and referred to an Auditing Committee, consisting of Drs. S. H. Freeman, of Albany, D. F. Dayton, of Potsdam, and J. C. Spencer, of Watertown, which subsequently reported that they had examined the accounts and vouchers, and had found them correct.

Some discussion arose concerning the "Transactions," and the fact was made prominent that the County Medical Societies were "*expected and required*" "to purchase each year a number of copies of the Transactions equal to five times the number of delegates it is entitled to send to this Society."

MERRITT H. CASH PRIZE FUND.

Total, $695.89, on deposit, reported by Dr. Porter, Treasurer.

REPORT OF COMMITTEE ON PRESIDENT'S ADDRESS.

Dr. W. W. Potter, Chairman, reported that the place of holding the meetings could be safely intrusted to the Committee of Arrangements; that the division of the Society into sections for scientific work was at present inexpedient; that the business could be facilitated by the appointment of a committee of three by the President at the last session of each annual meeting, to which preparation of the programme for the next meeting could be referred; and that a circular be issued after the Executive Committee of the International Medical Congress had announced the ratio of representation from the societies entitled to send delegates, in order that the question might be clearly understood and the Society be able to take the steps necessary to secure the scientific, social, and official relations with that scientific organization to which this Society is entitled. The report was accepted and adopted.

Dr. A. C. Post, of New York, then read a paper

ON SENILE HYPERTROPHY OF THE PROSTATE,

in which he described the varieties of the affection, the pathology, the symptoms to which they gave rise, the methods of diagnosis, and the treatment. Special attention was directed to withdrawal of residual urine, once, twice, or more frequently, daily, by means of the catheter.

Dr. Post also exhibited a hard-rubber syringe which he had devised for washing out the bladder, "Post's vesical syringe."

The securing of a full size of the urethra anterior to the prostate is the most important point in treatment. If the solid catheter was used *great care* should be taken in instructing the patient how to use it properly.

In cases of large quantity of residual urine, it is not safe to withdraw all of it at the first use of the catheter. In cases in which it is very difficult to introduce the catheter, the instrument may be left in position for twenty-four or forty-eight hours. A large number of catheters were exhibited, which had been devised for overcoming the obstacles incident to local treatment, as false passages, excessive narrowing of the urethral canal, etc.

Dr. T. H. Squires, of Elmira, spoke of the treatment of prostatic retention, and he believed that in all cases, the bladder could be emptied without special skill. In most cases the soft catheter, or solid catheter of large size, can be used successfully, and in addition he would suggest gum-elastic catheters of large size and large curve.

Dr. Vanderveer, of Albany, thought that the catheter should be used from the development of the first symptoms. He preferred the silk-web catheter, and also the fountain syringe, filling the bladder to comfortable distention and allowing it to run out.

Dr. Knapp, of New York, said that cocaine had been used successfully, rendering catheterization substantially painless.

Dr. Lucien Howe, of Buffalo, gave a

DEMONSTRATION OF THE ELECTRIC LIGHT,

and spoke of its uses in surgery, and in examinations of the eye.

MEMBERS BY INVITATION.

Dr. W. H. Bailey, of Albany, announced the following: Drs. H. S. Case, J. J. Flint, J. H. Skillicorn, of Albany, J. D. Lomax, A. A. Roberts, and S. F. Rogers, of Rensselaer County, C. M. Lefler, of Fulton County, and C. M. Wilson, of St. Lawrence County.

Dr. F. M. Hamlin, of Auburn, then read a paper on

THE OPIUM HABIT,

which contained a careful *résumé* of what was known concerning this subject, together with his experimental experience in the use of the drug. Insanity seldom results from the habitual use of opium. He favored the sudden-reduction method of breaking the person of the habit.

Dr. William Hailes, of Albany, demonstrated the method of making

CULTURE EXPERIMENTS IN BACTERIA.

The culture-tubes were exhibited, of Koch, of Sternberg, which he preferred, and he described the method of introducing the materials to be examined, etc.

Dr. A. M. Phelps, of Chateaugay, made a brief communication, in which he described

A METHOD OF OPERATING FOR HARE-LIP, WHICH LEAVES THE SCAR IN THE MESIAN LINE AND MAKES AN ARTISTIC LIP.

It was admissible only in cases where one-fourth of the lip remained.

The Society then adjourned to meet at 3 P.M.

AFTERNOON SESSION.

The Society was called to order by the President, and the Society proceeded with the special order, namely, consideration of

AN ACT ENTITLED AN ACT TO ESTABLISH A BOARD OF MEDICAL EXAMINERS OF THE STATE OF NEW YORK.

Dr. Jacobi, of New York, who introduced the bill, stated that he had been informed that the Special Committee had arrived at a conclusion which had received the support of all its members. He, therefore, gave way for the supplementary report of the Special Committee, and

Dr. H. G. Piffard, of New York, made a statement, and asked for the passage of a resolution which instructed the Standing Committee on Legislation to prepare a bill covering the following points, and submit it to the Legislature as promptly as possible; to provide for *one* Board, consisting of *nine* members to be appointed by the Regents of the University, six from the Medical Society of the State of New York, *three* of whom shall be from incorporated medical colleges, and the other members from the two other incorporated medical societies of the State; that the Board shall be appointed annually, without disqualification for reappointment by reason of having served one or more years; that examination shall be on anatomy, physiology, and hygiene, chemistry, pathology, and practice of medicine, surgery, midwifery, and therapeutics; that the salary of each member of the Board shall be nine hundred dollars; that the examinations be conducted anonymously.

The resolution was adopted unanimously, and was followed by votes of thanks to the Special Committee, on motion by Drs. Sturgis and Jacobi, of New York.

REPORT ON COMMUNICATIONS FROM COUNTY MEDICAL SOCIETIES.

Dr. Piffard, Chairman of the Temporary Committee on By-Laws, reported progress on *two* communications received from the Medical Society of the County of New York, and approving of the amendments to the by-laws of that Society adopted at their last annual meeting.

The communication from Dr. Charles Jewett, of Kings County, was referred to the Committee on Legislation.

The report was accepted and adopted.

Dr. Charles H. Porter, of Albany, introduced a resolution recommending that the Committee on Legislation be instructed to have introduced into the Legislature

AN ACT TO PERMIT THE SOCIETY TO CONTROL ITS OWN MEMBERSHIP.

The resolution was unanimously adopted.

Dr. W. F. Mittendorf, of New York, read a paper on

GRANULAR LIDS,

in which he directed attention especially to the beneficial effects produced by the local use of balsam of copaiba, muriate of hydrastin, and tannin.

PAPERS BY TITLE.

By Dr. H. Jewett, of Canandaigua; Dr. F. P. Foster, of New York; Dr. P. F. Mundé, of New York; Dr. W. E. Bullard, of New York; Dr. W. B. Chase, of Brooklyn; Dr. J. S. Warren, of New York; Dr. O. D. Pomeroy, of New York; Dr. A. Jacobi, of New York; Dr. G. G. Monroe, of Crary's Mills; Dr. W. G. Tucker (biographical sketch of Dr. Jacob S. Mosher, of Albany); Dr. J. O. Roe, of Rochester.

Dr. Alfred Mercer, of Syracuse, reported

TWO CASES OF LIGATURE OF THE FEMORAL ARTERY.

The paper was discussed by Dr. A. C. Post, of New York.

Dr. F. N. Otis, of New York, gave a demonstration of the working of his

NEW INSTRUMENT FOR EVACUATING THE BLADDER IN LITHOLAPAXY.

Dr. Otis made an additional communication

ON STRICTURE OF THE URETHRA,

in which he referred to the ratio existing between the circumference of the penis and the calibre of the urethral canal, the size of the meatus, the observation that prostatic enlargement was associated with contracted orince, the reflex disturbances accompanying a narrow urethral orifice and apparently cured by restoring the meatus to the normal size, the important point that instruments used for dilating urethral strictures should not be introduced into the bladder unless associated with stricture posterior to the triangular ligament, that ninety per cent. of all strictures are anterior to the triangular ligament, and that *close* strictures in the deep portion of the urethra are spasmodic in character, and that when division of the stricture was *complete* the cure was permanent.

The paper was discussed by Dr. A. C. Post, of New York, who agreed with Dr. Otis in the statement that the first step to be taken was to clear up the strictures in the anterior part of the urethra in all cases, except when retention demanded immediate operative interference.

Dr. Vanderveer, of Albany, spoke favorably of Dr. Otis' new *evacuator*, and also agreed with him concerning the treatment of urethral stricture.

The paper was referred to the Committee on Publication.

Dr. A Jacobi, of New York, reported on the

COMMUNICATION FROM THE NEBRASKA STATE MEDICAL SOCIETY,

that the secretary be directed to inform Dr. R. R. Livingston, of Platsmouth, Neb., that he is the recognized and accredited representative in the Nebraska State Medical Society from this Society.

Dr. Jacobi also directed attention to the subject of

COLLECTIVE INVESTIGATION OF DISEASE

directed by the last International Medical Congress, and stated that the committee, consisting of Dr. N. S. Davis, of Chicago, and himself, would soon issue a circular concerning "Rickets," to which he hoped every member of the profession would respond, thus aiding in the collection of material for the coming Congress to be held at Washington.

Dr. Joseph E. Winters, of New York, read a paper on

MATERNAL AND INFANT NURSING,

in which wet-nursing was unconditionally condemned.

Dr. A. N. Bell, of New York, referred to statistics which substantiated the fact that the rate of mortality in infant life was least among those who have been nursed by the mothers.

Dr. W. S. Ely, of Rochester, did not believe that the rate of mortality was greater with healthy wet-nursing than with maternal nursing, and regarded the evidence as defective which had been adduced to support the view advanced by the author of the paper.

Dr. Townsend, of Albany, regarded wet-nursing a the only safe resource in very many cases.

Dr. A. Jacobi, of New York, regarded the paper as a sensational communication, in that it disagreed with what almost every authority on the subject had stated to be fact, and was based upon a number of anecdotes from history, etc. He believed that for infants mother's milk should rank first, nurse's milk second, and artificial food third.

Dr. Mittendorf, of New York, believed that the facts were against the conclusions reached by Dr. Winters.

Dr. Winters closed the discussion, stating that he had given the statistics from the institutions to which Dr. Mittendorf had referred, and that they sustained his views, and that, when his paper was published in full, it would be seen that it contained only attested facts, and therefore that it could not be called sensational unless facts were sensational.

The paper was referred to the Committee on Publication.

Dr. Wm. C. Jarvis, of New York, then demonstrated

A NEW METHOD OF ELECTRICAL ILLUMINATION OF THE THROAT,

by means of the Foster electric cell.

It was discussed by Dr. Goff, of Cazenovia.

The communication was referred to the Committee on Publication.

MEMBERS BY INVITATION.

F. B. Hough, Lewis County; W. W. Seymour, Rensselaer County; G. L. Ullman, F. D. Morrill, and J. W. Riley, of Albany; R. H. Sabin and W. B. Sabin, of West Troy; H. V. Hull, of Schenectady, and R. W. Warner, of Ilion.

Dr. Ward, of Albany, introduced a resolution asking for an appropriation of one hundred dollars for the use of the Committee on Legislation during the ensuing year. Adopted.

Dr. Vanderveer, of Albany, then read a paper on

TAIT'S OPERATION,

in which he described in detail the successive steps in the operation as he witnessed them during its performance. He then reported several cases and exhibited specimens removed by Mr. Tait. He also reported five cases of his own.

The paper was discussed by Dr. Baker, of Lockport; Dr. Phelps, of Chateaugay, and Dr. A. C. Post, of New York, the discussion being chiefly on the use of antiseptics in surgery.

The Society then adjourned to meet in the Assembly Chamber at eighto'clock.

EVENING SESSION.

The Society met in the Assembly Chamber, and was called to order by the Vice-President, DR. P. R. H. SAWYER, of Bedford, Westchester County.

THE PRESIDENT then delivered the annual address, taking for his subject

MEDICAL EVIDENCE.

An eminent writer [1] says, "A doctor who knows nothing of law and a lawyer who knows nothing of medicine are deficient in essential requirements of their professions."

The object of jurisprudence is the discovery of truth; and the whole range of science, physical and moral philosophy, medicine in its widest sense, everything which experience has established or can discover, are rendered subservient to justice. While there are no limits to the sources and objects of evidence, certain rules have been adopted which restrict its admission. These rules are rigid, and too numerous and complicated to be discussed here.

An expert is selected by the court, or the parties concerned, for his supposed special knowledge or skill in particular matters to which he is to testify, or make a report embodying his opinions.

I cannot better define the duties and requirements of the expert than to quote in full from Elwell:

"Extra knowledge on questions of science, skill, trade, business, or other matters requiring special knowledge, qualifies the person thus informed to give *opinions* in courts of justice. This is contrary to the general rule that the witness must confine himself to facts, and leave the conclusions of those facts to be determined by a court or jury under oath. An opinion is the judgment which the mind forms on any proposition, statement, theory, or event, the truth or falsehood of which is supported by a degree of evidence that renders it probable, but does not constitute absolute knowledge, truth, or certainty.

"These opinions or conclusions of judgment which make up such opinions of experts, are the same in substance as the verdict of a jury or judgment of a court, which is nothing more than the opinion of such jury or court as to what is established by the facts in the case. This conclusion or opinion, in the latter case, is given under the sanction of an oath; so is that of the expert. There is this difference, however, in the two cases. The court or jury is under oath while they are making up their opinions upon the facts in the case, and these facts upon which the opinion is predicated are also submitted to the minds of counsel and parties. The facts are also given by the common witness under oath, upon which the jury or court makes up an opinion. The expert, on the other hand, comes to the results constituting his opinion, which is to be received in evidence, from his own private study, observation, and reflection. He is not under oath when he weighs his facts, and however anxious he may be to arrive at correct conclusions, he is not under the significant and impressive obligation of an oath to do so; and though the facts upon which the witness' opinion is based may be called for by counsel, yet from the very nature of the case it is not to be expected that the jury or the court will understand them."

Importance of medical evidence.—No man, be he professional or layman, is properly qualified to appear as a witness without some knowledge of his duties, and the rights pertaining thereto.

The medical man, as a witness, is subjected to the most rigid criticism as to what he says, how he says it, and why he says it, and also to all the influences that may have a bearing upon it. This criticism comes not only from the opposing counsel, but also from the party by whom he is called, and he is thus placed, as it were, between two fires, from which he is fortunate if he escapes without being wounded, and especially so if he is an important witness.

Ignorance and deception may triumph in the sick-room, where it is not cross-examined, while in open court it can find no protection and must be exposed. The medical witness must understand the general rules of evidence, without which he is sure to meet with interruptions and chagrin, if not disgrace. No one should presume to enlighten the court and jury in a difficult case, unless he is able to do so. He may be compelled to attend court, like other witnesses, but no witness is compelled to testify to what he don't know, and if he is not qualified, the safe and honorable course is to acknowledge it.

Duties and responsibilities of medical witnesses.—While works on medical jurisprudence must be studied and analyzed, it is not in them that the medical witness will find the directions he needs to prepare him for the important duties of making up and giving opinions, that are to be received as facts, by the court and jury.

In a report made to the American Medical Association, the writer, in speaking of the medical witness, uses the following language: "If, however, he concludes to form an opinion and testify, there are certain rules and regulations which he should adopt, not only to give force to his testimony, but for his own protection.

"1. He should listen attentively to the testimony, as to all the facts in the case, and avail himself of every authentic means of forming a correct opinion.

"2. He should studiously guard against being biased, either by popular clamor, or because he is called by one side rather than the other.

"3. The medical witness is not to take into consideration the influence which his testimony may have on the prisoner at the bar, or the case under consideration.

"4. The expert is called to testify as to the bearing of the testimony given, and though he may have his own doubts of the truth of the testimony, yet, if it stands unimpeached, he must receive it as truth.

"5. A medical witness should not assume the province of the jury.

"6. The medical witness should have his mind fully prepared, before taking the stand, as to what he can testify to, and his reasons, if they are required."

The medical witness is rarely called upon to testify to facts, as gathered by the exercise of his senses; but to give the deductions drawn from the facts given by others. These facts may be new to him, and may be drawn from any part of the wide domain of science; yet he may be called upon to give an opinion, with no time for reflection, or for reference to authority; while counsel who manage the case have plenty of time to familiarize themselves with the authorities and with all the evidence bearing upon the case. The common witness has simply to state the facts within his personal knowledge, but the medical witness must know the facts first, constituting the case upon which his opinion is desired; he must apply to these facts his special knowledge, and from this reach a conclusion in his own mind, and give this opinion to the jury. He should never permit himself to be drawn into a discussion while upon the stand.

Before answering a hypothetical question the witness should weigh every word and see that there is no confusion or contradiction of terms or language, and then confine his answer closely to the supposed case. The courts require a hypothetical question to contain only facts that are in the case, and the expert says what they prove scientifically.

If the question involves an impossibility, as it sometimes does, the witness should decline to answer until a definite case is put.

A vote of thanks was tendered the President for his address, and the Society adjourned to meet in the banquet hall at the Delavan.

[1] David Paul Brown.

THIRD DAY—THURSDAY, FEBRUARY 5TH—MORNING SESSION.

The Society was called to order by THE PRESIDENT.

Prayer offered by DR. POST.

DR. POTTER, of Buffalo, Chairman of the Committee on the Inaugural Address, reported that they had received a communication from the New Jersey State Medical Society concerning the preliminary education of medical students. The report was accepted and referred to a Special Committee, consisting of Drs. S. O. Vander Poel, J. O. Roe, and A. M. Phelps.

The Committee on Publication recommended that County Medical Societies change the time of holding their annual meetings.

DR. STODDARD, of Rochester, moved that the County Societies be requested to hold their annual meetings in other than the first three months of the year, and that the volume be published in two parts: the first part consisting of proceedings and scientific papers, and the second of a list of members of County Societies, the membership of this Society, together with all laws affecting the medical profession. Adopted.

DR. KENDALL, of Baldwinsville, offered a resolution authorizing the President and Secretary to appoint delegates to the State Medical Societies, *ad interim*. Adopted.

A communication from Richmond County concerning the Code and State Board of Examiners, accepted and placed on file.

DR. WARD, of Albany, moved a vote of thanks to the Agricultural Society for the use of their hall. Carried.

DR. POTTER, of Buffalo, offered a resolution requesting the Committee of Arrangements to arrange with railroads, as far as possible, for reduced rates to members attending the annual meetings. Adopted.

DR. VANDER POEL, of New York, addressed the Society on the question

WILL QUARANTINE PROTECT AGAINST CHOLERA?

The disease had spread from Mecca because of the opposition to quarantine made by England. Germs of cholera may lie dormant for a long time, which explains the apparent spontaneous development. Quarantine is practically useless. Prevention of the spread of cholera depends upon local hygiene in all its details. Thorough medical inspection of persons and clothing before going on shipboard, also while on board, observing disinfection and cleanliness, and on arrival, absolute isolation of the well passengers in a building of observation and daily inspection, and removal of sick to the Cholera Hospital. Detention without symptoms for ten days at New York, Philadelphia, New Orleans, or Baltimore, is sufficient to prevent the spread of cholera in this country. Action should be taken at once, and without a moment of delay.

DRS. POST, of New York, and BOWDITCH, of Boston, also discussed the subject.

DR. WARD, of Albany, offered a resolution, that it is the sense of this Society that the United States Government should take steps to enforce sanitary measures at foreign ports where cholera exists, and that the resolution be forwarded to the President of the United States, accompanied by the remarks made by Dr. Vander Poel. Adopted.

Papers were read by title from Drs. Tuttle, of Poughkeepsie; Hopkins, of Brooklyn; Swinburn, of Albany; Parker, of Poughkeepsie; Sturgis, of New York; Howe, of Buffalo; Chapin, of New York; and Jacobi, of New York.

The report from the delegates to the International Congress was accepted and referred.

DR. LOW, of Oswego, read a paper on

CRANIOTOMY AND ABDOMINAL DRAINAGE,

which was discussed by Drs. Vanderveer, of Albany, and Post, of New York.

DR. W. W. POTTER, of Buffalo, Chairman of the

COMMITTEE OF NOMINATION,

made the following report:

President—Albert Vanderveer, of Albany.

Vice President—Alfred C. Post, of New York.

Secretary—William Manlius Smith, of Syracuse.

Treasurer—Charles H. Porter, of Albany.

Censors—Southern District: F. A. Castle, George H. Fox, David Webster, of New York. Eastern District: Joseph Lew, M. L. Snow, of Albany; Leroy McLean, of Troy. Middle District: A. Churchill, of Utica; L. Griffin, of Binghamton; Robert Frazier, of Camden, Western District: Theodore Dimon, of Auburn; M. G. Kittinger, of Lockport; David Little, of Rochester. Medical College, Syracuse University; I. N. Goff, of Casenovia.

Committee of Arrangements.—A. B. Ward, of Albany; W. S. Ely, of Rochester; E. L. Partridge.

Committee on By-Laws.—W. C. Wey, of Elmira; H. G. Piffard, of New York; W. Manlius Smith, of Syracuse.

Committee on Hygiene.—E. V. Stoddard, of Rochester; F. C. Curtis, of Albany; A. N. Bell, of Brooklyn; G. J. Fisher, of Sing Sing; E. Hutchinson, of Utica; W. H. Bailey, of Albany; J. O. Creveling, of Auburn.

Committee on Legislation.—Daniel Lewis, of New York; S. B. Ward, of Albany; F. R. S. Drake, of New York.

Committee on Medical Ethics.—A. Jacobi, of New York; Arthur Mattheson, of Brooklyn; J. W. Whitbeck, of Rochester.

Committeee on Prize Essays.—W. W. Potter, of Buffalo; W. S. Ely, of Rochester; H. R. Hopkins, of Buffalo.

Committee on Publication—W. M. Smith, of Syracuse; Charles H. Porter, of Albany; Alfred Mercer, of Syracuse.

Permanent Members—First District: G S. Hopkins, of Kings County; J. S. Warren, of New York; Wesley M. Carpenter, of New York; E. N. Chapman, of Kings County; John G. Curtis, of New York. Second District: A. M. Campbell, of Westchester; H. R. Winter, of Ulster. Third District: John M. Bigelow, of Albany; J. D. Lomax, of Troy. Fourth District: C. M. Wilson, of St. Lawrence; A. W. Suiter, of Herkimer. Fifth District: George Seymour, of Oneida. Sixth District: T. C. Edson, of Broome; E. Allison, of Steuben. Seventh District: John Gerin, of Cayuga. Eighth District: Peter Faling, of Niagara; H. R. Hopkins, of Erie.

Honorary Members—J. L. Cabell, of Virginia; F. J. Whittaker, of Ohio; J. G. Wormley, of Philadelphia; J. S. Clouston, of Edinburgh, Scotland.

Delegates—Massachusetts Medical Society: M. L. Bates, of Columbia; B. F. Sherman, of St. Lawrence; Frank P. Foster, of New York; Peter Faling, of Niagara; John Gerin, of Cayuga. Connecticut Medical Society: Henry March, of Albany. Pennsylvania Medical Society: S. H. Freeman, of Albany. Vermont Medical Society: C. S. Merrill, of Albany. Canadian Medical Association: J. O. Roe, of Rochester; J. Gerin, of Auburn. New Jersey Medical Society: W. Gill Wylie, of New York; J. P. Creveling, of Cayuga. Ontario Medical Association: Lucien Howe, of Buffalo. German Association of Naturalists and Physicians: Charles H. Starr, of Rochester.

The incoming President appointed W. W. Potter, of Buffalo; Daniel Lewis, of New York; A. M. Phelps, of Chateaugay, a Preparatory Business Committee to facilitate work at next annual meeting.

The thanks of the Association were tendered to the President, the Committee of Arrangements, and the Business Committee.

A communication from Cayuga County received and referred to the Committee on By-Laws.

Adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 14, 1885.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

CASES OF SALPINGITIS—RESULTS OF OPERATION.

DR. W. GILL WYLIE exhibited a number of specimens of salpingitis removed by laparotomy, and made the following remarks:

"MR. PRESIDENT: I will read short histories of fourteen cases of salpingitis which I have operated upon since May, 1883, and I have here for presentation the specimens from twelve of these cases, with a report on each by Dr. Henry C. Coe, Pathologist to the Woman's Hospital of the State of New York. Nine were operated on in Bellevue Hospital and five in private practice. Twelve of the fourteen recovered, and two died from the effects of the operation. Both of the latter were hospital cases, and both died on the fifth or sixth day from septicæmia.

"CASE I.—Mrs. R——, aged thirty-two, married, the mother of two children, has had two miscarriages. Her present trouble dates from an abortion, three years ago, although she has always suffered from more or less dysmenorrhœa. She complains now of severe dragging pains on both sides of the pelvis. Two years ago she underwent an operation for lacerated cervix. Examination reveals the uterus movable, but retroverted, the tubes and ovaries prolapsed, sensitive, enlarged, and easily made out, while by slowly pressing the left tube a gleety pus can be made to appear in the vagina. Operation, May 26, 1883. She made a good recovery from operation.

"*Examination of specimens.*—Both tubes are found dilated and adherent to the corresponding ovaries, which appear to be the seat of a chronic ovaritis. The distal end of one of the tubes has been so fused with the ovary, as the result of old inflammations, that the fimbriæ and opening have been entirely obliterated. In the other tube, which is less dilated, the lumen is patent. Microscopic examination of the contents of the most diseased tube showed it to consist largely of pus and fatty degenerated epithelial cells. A few ciliated cells were also noticed. A small amount of pus was observed in the fluid taken from the other tube.

"Notwithstanding the fact that both tubes were completely removed, the patient has menstruated, with one or two exceptions, regularly every month. The amount of flow became excessive, lasting eight or ten days. She was curetted; but three months later, after menstruating regularly, it was necessary to curette again, and nine months later curetting was repeated. Granulations were found each time, but nothing malignant was discovered by a careful examination made by Dr. W. H. Welch. Now, nearly two years after the operation, she still menstruates every month, but is able to go about, and except for a ventral hernia would be comparatively well. The uterus is a little above the normal size.

"CASE II.—M. L——, aged twenty-five, a native of France, married, but no childen. Was admitted May 30, 1883. She gave a history of gonorrhœa, and complains of pain over the ovaries, dysmenorrhœa, and leucorrhœa. On examination the uterus was found retroverted, and after some treatment a prolapsed tube and enlarged ovary were also discovered. Operation, June 25, 1883. The patient made a good recovery, but still complained of pains, notwithstanding both ovaries and tubes were removed. She was kept under observation till September, and then discharged. It was afterward heard that she had a ventral hernia.

"*Examination of the specimen.*—Both ovaries and tubes were removed in the operation. It was found that the one ovary and the fimbriated extremity of its corresponding tube were so fused together that they could not be separated. The appearance presented was such as to suggest a normal tube terminating in a cystic ovary. On passing a probe through the cut end of the tube, a portion of this cyst is found to be the dilated tube, though the line of separation between the latter and the cystic ovary could not be made out. Many adhesions were also present. A drop of the watery fluid obtained from the tube was found to contain a small amount of pus, broken-down cells, and granular débris. Some ciliated cells were still preserved, as if they had been among the last to suffer disintegration. The condition in this tube was one rather of hydro- than pyo-salpinx. The other ovary was small and atrophied. The tube was distinct from the ovary. Its fimbriæ had entirely disappeared, and at the distal end there was a small but distinct cicatrix marking the site of the inflammatory process which obliterated the opening. A probe can be passed through the tube from the cut end, but is arrested at this artificial septum. The tube contains a reddish fluid, a drop of which shows, under the microscope, pus, broken-down cells, and granular débris.

"CASE III.—T. S——, twenty-seven years of age, a native of Italy, married, the mother of two children. Admitted April 28, 1883. She suffers from dysmenorrhœa and leucorrhœa. For more than a year she has had a severe pain in the right iliac fossa, which, since the birth of her last child in February last has been excruciating. She gives a history of gonorrhœa, which was confirmed by vegetations in the vagina. On examination the physical signs of a local peritonitis are found. Operation, October 28, 1883, shows a catarrhal state of the tubes and indurated ovaries. She made a good recovery, but still suffered much from the old pain, but gradually got better and was discharged cured December, 1883.

"*Examination of specimen.*—The ovaries [1] obtained from this case show a decided increase in the density of the fibrous stroma and thickening of the cortical zone. A few cysts are also present. The tubes are long and tortuous, but appear to be of normal size. Their fimbriated extremities are normal, and the lumina patent throughout. The specimen is so shrunken that it is impossible to say whether the tubes were originally diseased or not, probably they were not affected.

"CASE IV.—A. S——, a native of Ireland, thirty-one years of age, married, and the mother of two children. Admitted November 1, 1883. She is suffering from dysmenorrhœa. For the last ten years she has vomited several days every month, and besides suffers from severe pain in the right iliac region. Her general health is poor. On examination the uterus was found displaced to the left and more or less fixed; marked pelvic adhesions were present; the ovaries were sensitive. Operation, December 8, 1883. It showed that the omentum was adherent over the pelvic organs, and that both ovaries and tubes were fixed by fine adhesions. The pedicle was so short that both sides had to be tied a second time, and on the right side the arteries had to be picked up with artery forceps on account of the slipping of the ligature. To do this the abdominal opening had to be made larger and kept exposed for nearly an hour. All bleeding was, however, effectually stopped. The patient did not rally well, but there was little rise of temperature till the fourth day, when it steadily increased, and at the end of the fifth day had reached 106°. Death occurred from septicæmia.

"*Examination of the specimen.*—One tube showed but little change. It had become adherent to the ovary, probably as the result of an old peritonitis. There was marked dilatation and thickening near the fimbriated extremity, but the lumen was patent. The corresponding ovary was cystic. The opposite tube was considerably enlarged, its wall thickened, and dilated near the distal end. The fimbriated opening was buried in a mass of old adhesions. The fluid removed from this tube contained pus in small amount, granular epithelial cells, and a considerable amount of granular detritus. Several

[1] The specimen has been preserved for several months in chromic acid, and hence is nearly useless for gross examination.

groups of columnar epithelial cells were seen, a few of which still retained their cilia.

"This specimen was seen when fresh by Dr. Welch; he noted much congestion of the tubes, and marked pelvic peritonitis.

"CASE V.—Miss B——, a native of the United States, twenty-three years of age, single. She has suffered for several years from slight dysmenorrhœa and leucorrhœa. She gives a history of hystero-epilepsy commencing several years ago, and becoming more and more severe, till now she has sometimes a number of severe attacks each day. Physical examination showed the ovaries enlarged, and plainly to be felt, of the size of English walnuts. The uterus was movable and in its normal position. The tubes could not be made out as enlarged. Operation, December 3, 1883. The patient made a good recovery, without a single bad symptom. Both ovaries and tubes were removed.

"*Examination of specimen.*—Only one tube and ovary preserved. The ovary is of the size of an English walnut and extensively diseased. The capsule is thickened, and at the periphery a large cyst is seen. As the organ gives an obscure sense of fluctuation, it is doubtless cystic throughout. (The ovary in the specimen was entirely separated from the tube, and only a small piece, about one and a half centimetre, of the corresponding tube has been preserved, and this is hard to distinguish, except by laying it open and examining the lining mucous membrane under the microscope.) The fimbriated end was originally closed by a cicatricial mass, which was divided. There is a small cyst of the broad ligament just below the obliterated distal end. No fluid was found in the tube.

"CASE VI.—*Hydro-salpinx* (*hospital patient*).—M. B——, a native of Ireland, married, one child. Admitted, November 17, 1883. She is bed-ridden, and has been treated for menorrhagia. She complains of severe pain and tenderness over the left side. Examination shows the uterus retroverted somewhat, and a mass the size of a small hen's egg can be felt to the left of the fundus in the left broad ligament. Operation, January 27, 1884. Notwithstanding a slight rise of temperature the first three days after the operation, she made a good recovery. The left ovary and tube were found enlarged and diseased, but the right perfectly normal and free from adhesions, and were therefore left undisturbed.

"*Examination of specimen.*—Inspection of the diseased tube shows it to be enlarged to the size of a finger, and its walls much thinner than normal. Evidences of adhesion are to be seen all over its exterior. The distal opening has been entirely obliterated, evidently the result of previous inflammation. The accompanying ovary is enlarged to the size of an English walnut. It was evidently much larger before removal, as it contained a central cyst as large as a marble. The fluid found within the tube contained nothing but a large number of round and columnar epithelial cells. Many groups of well-preserved ciliated cells were found, looking as perfect as if they had just been removed.

"CASE VII.—L. D——, twenty-eight years of age, married but sterile. Admitted September, 1883. She suffers from dysmenorrhœa, has been bed-ridden for months at times, and has already been in four hospitals. She complains of pain in the back and head, and vomits almost every day. Her pulse is always over 100. For several years she has been unable to work, and is completely demoralized. When examined, the uterus was found retroverted fixed, the tubes and ovaries could be made out slightly enlarged. Operation, March 3, 1884. She did well for two weeks, when the temperature rose to 104°, but this was unaccompanied by pain or tenderness. She had also a slight cough, and this, together with the elevated temperature, was regarded of pulmonary origin. Gradually, however, she got stronger, and was discharged cured September, 1884.

"*Examination of specimen.*—The ovaries are found to be of normal size, but cystic. The corresponding tubes are enlarged and dilated. The condition is nearly the same as in Case I., except that here both distal apertures seem to have been obliterated by old inflammation. One tube is closely adherent to the corresponding ovary, the other only partially. They both give a distinct sense of fluctuation, and on introducing a needle, a watery fluid is obtained which shows under the microscope a few mucous corpuscles and normal epithelial cells. A considerable number of perfect ciliated cells were also present. The condition may be termed one of moderate hydro-salpynx.

"CASE VIII.—Mrs. Mc——, a native of the United States, aged twenty-seven, married, and has had one miscarriage at four months, but no children. She has suffered greatly from dysmenorrhœa and menorrhagia. Her general health is poor, and she has been a confirmed invalid for the last ten years, being confined to bed most of the time. She complains also of an almost constant pain in the iliac region, back, etc. Examination shows the uterus anteverted; the left ovary and tube enlarged and adherent; the ovary also enlarged. Operation, March 13, 1884, and it was found that the right ovary was slightly adherent and cystic, while the left tube and ovary were enlarged and very firmly adherent. The patient recovered without a single bad symptom. Examination of the removed tubes and ovaries showed the one tube and ovary normal to all appearances, although the wall of the tube seems to be a little thicker than usual. The other tube was uniformly enlarged, and its mucous membrane swollen. The lumen was patent, bnt no fluid was present. The corresponding ovary was enlarged and cystic. The condition was probably one of catarrhal salpingitis, leading to hypertrophy of the mucous membrane, and, perhaps, also of the muscular layer of the wall of the tube.

"CASE IX.—H. D——, colored, a native of the United States, aged twenty-seven, married, but sterile. Admitted February 3, 1884. She is suffering from dysmenorrhœa, and has had severe local pains in the left iliac region for the past three years, making her a complete bed-ridden invalid. Examination showed the uterus anteflexed and firmly fixed, and the enlarged ovaries and tubes could be felt, especially on the left side. Operation, March 20, 1884. She had adhesions, about the worst I ever saw, the omentum, bladder, intestines, etc., being all involved. A pedicle on the left side could not be secured, and the arteries were picked up by forceps, necessitating a prolongation of the operation and exposure of the peritoneum. She gave symptoms almost identical with Case IV., and died of septicæmia on the fifth day. Both tubes and ovaries were removed in the operation.

"*Examination of specimen.*—Both tubes were found to be enlarged and thickened, but not dilated. They were buried in masses of adhesions, though the lumina seemed to be open. Both ovaries were the seat of marked cystic degeneration. In one broad ligament was a cyst the size of a large walnut. Microscopic examination of the mucous membrane of the tubes showed it to be much swollen and covered by leucocytes. No epithelial cells were preserved. In this case there had probably been a chronic catarrh of the tubes, which led to thickening of the mucous membrane. Some of the thickening could also be attributed to an old peri-salpingitis.

"CASE X.—Mrs. O——, aged twenty-five, married two and a half years, but sterile. Before marriage she was perfectly well, but soon after this she began to suffer from dysmenorrhœa and leucorrhœa. For more than a year she has had severe pains first on the right and then on the left side. Lately she has also suffered from menorrhagia. Examination showed the uterus anteverted and imbedded in a mass of indurated tissue, and the enlarged ovaries and tubes could be also made out. She was kept under observation and treatment for a year previous to operation. The operation was performed May 1, 1884. The omentum was found covering all the

pelvic organs. Both ovaries were imbedded in a mass of adhesions and very much enlarged. The left ovary was of the size of a lemon and filled with abscesses. The corresponding tube is firmly adherent and infiltrated with pus. The right tube and ovary are not as much enlarged, but a number of small pus-centres were noticed as the adhesions were broken up. The patient made a good recovery, except that an abscess formed around the stump on the left side and the track of the drainage-tube discharged for several months. Pyo-salpinx and ovaritis. Specimen accidentally thrown away.

"Case XI.—M. H——, aged thirty-two, married, and has had one child and three miscarriages. Admitted September, 1884. She is suffering from dysmenorrhœa. She had a miscarriage six months ago, and for nearly two months has had a septic fever. She complains of a severe pain in the iliac region. On examination the uterus is found retroverted; the ovaries and tubes enlarged and sensitive. Operation, October 9, 1884. Extensive adhesions were found, the omentum, small intestines, etc., being involved. The tissues of the tubes and of one ovary were so softened and infiltrated that the ligature cut entirely through the pedicle, and the blood-vessels had to be picked up and tied separately. Abscesses on both sides, involving the ends of the tubes, were met with. A drainage-tube was inserted and the patient made an excellent recovery, and was discharged cured, November 18, 1884, all pains relieved.

"*Examination of specimen.*—The specimen obtained from this case is the best in the collection. It consists of two greatly enlarged tubes with their corresponding ovaries. The smaller of the tubes is about the size of a large lead pencil, and shows on its exterior evidences of previous inflammation. The accompanying mesosalpinx is much thickened. The fimbriated extremity of this tube is patent, so that on compressing the walls a quantity of thick, reddish-yellow fluid escaped. This on examination was found to contain pus, fatty degenerated epithelial cells, free fat, fatty acid crystals, and bits of smooth muscular fibres, but no ciliated cells. The other tube is as large as the forefinger, much distorted, and its fimbriated extremity buried in a mass of adhesions, which also partly envelop the ovary. The distal end is completely closed. The corresponding ovary is cystic; its cortex greatly thickened. There are many evidences of recent peri-oöphoritis. The opposite ovary is nearly normal in size and appearance. The fluid removed from the larger tube contains a large amount of pus and fatty degenerated epithelial cells, and much free fat. Groups of columnar epithelial cells are found, but no ciliæ are observed. There are numbers of spindle cells from the muscular layers, pointing to advanced changes in the wall of the tube. This is a typical example of pyo salpinx.

"Case XII.—Miss W——, twenty-eight years of age, single. She suffers from very severe dysmenorrhœa. She complains of pain in the back, head, neck, etc., and has been a confirmed invalid for several years. Examination showed the uterus retroverted and retroflexed, being held back by bands of adhesions, and very sensitive and boggy. The tubes could not be made out as enlarged. The ovaries are prolapsed and seem cystic. Operation, October 20, 1884. Extensive adhesions were found, although the tubes were the principal bands holding back the uterus. They were thickened, but not distended. The ovaries were cystic and fixed by adhesions. The patient made a good recovery. The specimen was lost.

"Case XIII.—Mrs. C——, a native of the United States, married, and the mother of one child. Admitted October 30, 1884. She suffers from dysmenorrhœa, and has had severe pain in the left iliac region since the birth of her child. On examination the uterus was found laterally flexed, and the enlarged left ovary and tube could be plainly made out in the left broad ligament. Operation, November 29, 1884. The left ovary and tube were removed (the right being normal). The patient made a good recovery and left well when discharged, December 28, 1884.

"*Examination of the specimen.*—The ovary is atrophied and buried in a mass of adhesions. The peritoneal surface of the tube is thickened, intensely congested, and covered with adhesions. The same is true of the mesosalpinx. The tube is enlarged to two or three times its normal size, its walls are thickened, and it gives, on pressing it between the fingers, an obscure feeling of fluctuation. The fimbriæ are still preserved, and the constriction of the lumen seems here to be at the proximal rather than distal end of the tube. On pressing the tube pus flows from the fimbriated end. This examined microscopically is found to contain a large number of pus corpuscles, fatty epithelial cells, and granular detritus. Several quite perfect ciliated cells were also seen.

"Case XIV.—M. C——, a native of Italy, married, has had three children and two miscarriages. Admitted October 15, 1884. She is suffering from menorrhagia, and complains of intense pain, chiefly in the right iliac region, for the last three years. On examination the uterus is found fixed and adherent, being drawn backward toward the sacrum. Under ether an enlarged tube can be plainly felt on the right side. Operation, December 8th. The patient made a good recovery and was discharged January 8th, the pain being completely relieved.

"*Examination of specimen.*—One ovary is about twice the normal size, and seems to be almost entirely made up of one large cyst. The other is considerably atrophied. The tube corresponding to the larger ovary is enlarged to twice its normal dimensions, and the fimbriæ have disappeared, the fimbriated opening being obliterated by old adhesions. The proximal cut end admits a large probe, and a drop of yellowish fluid can be squeezed from it, which shows, under the microscope, pus, broken-down epithelium (some with perfect cilia), and a large amount of granular débris. The other tube is enlarged, much distorted, and is bent on itself near the fimbriated end, so that the fimbriæ seem to spring almost from the middle rather than from the end of the tube. A probe may be introduced into the distal opening for a short distance. There are evidences of previous inflammation, leading to thickening of the mesosalpinx and peritoneal covering of the tube. A drop of fluid, obtained from the distended distal end, is shown by microscopic examination to contain a moderate number of pus corpuscles, many round, pyriform, and columnar ciliated cells, free nuclei, and granular detritus.

"The hospital cases were selected from patients presenting themselves for treatment at my clinic at the New York Polyclinic, where, during the past two years, I personally examined 607 individual women. Of this number 125 had unmistakable evidence of peri-uterine inflammation, and of these the tubes were plainly made out as enlarged in 18 cases on the first examination. By the use of glycerine and glycerine and alum tampons in many others of the 125, diseased tubes could be made out after the thickened peritoneal adhesions had been stretched and softened. In those cases where diseased tubes could not be defined by the touch, all other symp-

toms often indicated that they were diseased, and my studies lead me to the conclusion that peri-uterine inflammation which is not associated with diseased Fallopian tubes is the exception, and that. as a rule, disease of the tube precedes the local peritonitis."

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, December 2, 1884.

W. J. MORTON, M.D., PRESIDENT, IN THE CHAIR.

AN IMPROVED METHOD OF STAINING LARGE SECTIONS OF THE BRAIN.

DR. E. C. SEGUIN explained a method of aniline staining for large sections of the brain, which had given him very satisfactory results. It consisted in a modification of Sankey and Bevan Lewis' method. In order to insure the best effects, it was necessary to allow the sections to absorb the dye slowly. The solution employed was an aqueous one of aniline blue black, having strength of one to two thousand. In this the sections were completely immersed and allowed to remain for from twelve to sixteen hours. They were then washed, dehydrated, and mounted in balsam. He had not tested the value of this method for the study of minute histological details; but for examination with the naked eye he thought the method was superior to most others, especially in bringing out a sharp contrast between white and gray substances.

DR. STARR had tried aniline black for smaller sections, but had not been pleased with the results. Recently he had used Weigert's hæmatoxylin method and found it eminently satisfactory. He thought the two methods might be advantageously combined.

DR. WENDT remarked that such a combination would probably produce too great a mixture of colors, thus marring the distinctness of detail obtainable by either method when employed alone. Weigert's method was a good one, but required much care, skill, and time. As a general thing the simpler a method, the more satisfactory would be its every-day use.

DR. BIRDSALL was a believer in the chloride of gold for neuro-histological work. He was aware of its uncertainty; but the good specimens, which he had succeeded in preparing, were so beautiful as to compensate for the complete loss of other sections.

DR. SACHS said that the difficulty of a method was hardly a valid argument against its employment. He instanced the staining process of Freud, of Vienna, which brought out the nerve-fibres quite black, upon a purple background. The paths of the fibres thus became particularly well marked.

THE CIRCULATION IN THE BRAIN AS INFLUENCED BY ELECTRICITY.

DR. J. LEONARD CORNING read a paper with the above title. He first referred to some previous studies, undertaken in order to determine the therapeutic applicability of the mechanical regulation of the cerebral circulation, the results of which were published in THE MEDICAL RECORD of February 18, 1882. The instrument which he at first devised had since been improved upon. The essential features of the new appliance consisted in a metallic fork, having a handle four inches long, and provided with two prongs resembling those of a large tuning-fork. To the extremity of each of the prongs was attached a narrow sponge electrode. The prongs could be made to approximate or separate from each other at will by simply rotating the screw in the handle. It was thus possible, when the instrument was held at right angles to the neck, to adjust each pad with great accuracy over the corresponding carotid. When a galvanic current was conducted to these small electrodes by means of a bifurcated rheophore, secured to the negative pole of a galvanic battery, while the positive electrode was placed below the occiput, it transpired of necessity that all the structures interposed within the circuit were more or less affected. As a natural consequence the most pregnant expression of the activity of the electric current would be found in a greater or less modification of the functions of the involved nerves, namely, the sympathetic and pneumogastric.

The physiological results obtained in this way were due to: 1, Arterial pressure; 2, contraction of the cerebral capillaries; 3, retardation of the heart's action. Besides these, we should doubtless have to include effects produced by threads of current upon the medulla, as well as collateral phenomena not easily amenable to analysis. Thus the phenomena which he had succeeded in evoking by the aid of this instrument were substantially as follows:

1, Dilatation of the pupil; 2, drowsiness; 3, dizziness (where strong currents and considerable pressure are employed); 4, drooping of the eyelid; 5, retardation of the heart's action (where exclusively strong currents are employed); 6, pallor about the lips and frontal region; 7, muscular weakness, as proven by the dynamometer—the subject, if standing, complains of weakness in the knees; 8, in anæmic individuals syncope may be produced, should excessive pressure and strong currents be employed; 9, the excitement incident to the primary stage of etherization is cut short by resort to this method.

Having employed the instrument described in a variety of neuroses, particularly in migraine and epilepsy, with more or less success, the thought occurred to him that the efficacy of the procedure might perhaps be enhanced if some means were devised by which compression and galvanization could be employed for more or less prolonged periods of time.

Accordingly, after many trials, he devised an appliance which appeared to fulfil all reasonable indications. It consisted in the first instance of an elastic belt, which encircled the neck, and to the centre of which was secured a framework of metal, resembling somewhat in shape that of a horse-shoe. To the extremity of each branch of this apparatus was secured, by means of a ring and screw, a narrow, adjustable electrode, insulated by the interposition of a thin segment of hard rubber. The branches might be dilated or approximated at will by the aid of a screw which protruded anteriorly through the centre of the elastic belt.

In order to adjust the instrument the branches were placed on either side of the larynx in such a manner that each narrow electrode rested above the corresponding carotid. The branches were then carefully adjusted by the aid of the screw. The belt was then tightened and secured behind by means of appropriate buckles. The pressure was only carried to a sufficient extent to insure slight compression of the lumen of the artery, and not to such a degree as to cause the slightest inconvenience to the patient. By means of a bifurcated rheophore both electrodes were secured to the negative pole of a galvanic battery. A broad electrode, which was appropriately secured to the belt, was now placed upon the posterior aspect of the neck, and attached by a single rheophore to the positive pole of the battery. The current was then gradually increased, great care being taken in the execution of this portion of the operation. A water rheostat should be employed if possible, and the procedure should never be carried to such a degree as to produce tinnitus, dizziness, or extreme pallor about the ears and face.

In closing, Dr. Corning said: "I have employed the above apparatus in the treatment of a large number of neuroses. In epilepsy, congestive headache, mania, insomnia, and the convulsions of children it has surpassed my most ardent expectations. In the hyperæmic conditions of the brain incident to the prolonged abuse of alcoholic stimulants, and in other forms of vaso-motor insufficiency its prolonged employment has yielded excellent results. A noteworthy circumstance is the fact that the primary stage of excitement incident to etheri-

zation is effectually aborted by the use of electro-compression; and, indeed, the same may be said of simple pressure applied to the stems of both carotids, as abundantly shown by the observations of my friend, Dr. M. J. Roberts, of this city. Dr. Chichester, of New York, also tells me that he has succeeded in causing a permanent diminution in the rapidity of the heart's action in a patient suffering from exophthalmic goitre, by employing one of my instruments for electro-compression. Besides the above effects, which speak for themselves, I have recently had occasion to obtain additional proof of the pronounced influence exercised by this procedure upon the cerebral circulation. I applied the instrument to the neck of an infant whose fontanelle was still open, and observed that, when an interrupted galvanic current was employed, there was a perceptible sinking of the tissue above the opening.

"These phenomena are conclusive, even when interpreted in the light of the most guarded conservatism. Taken in conjunction with the results obtainable at the bedside, they may be urged in extenuation of the present researches in the cause of physiological therapeutics."

Dr. Rockwell said that he had no doubt that by electro-compression the brain and sympathetic system could to a certain extent be affected. But the main action of the apparatus was restricted to the surface. He did not believe that the cerebral circulation could be seriously disturbed by it. In all such investigations the varying degree of susceptibility should be taken into account. After applying electricity to the head some would experience profound drowsiness, others would feel scarcely anything. He did not know whether the results were due to direct cerebral action, or depended upon the intermediate agency of the circulation. He thought that perhaps electro-compression might prove a valuable adjunct to other treatment, just as galvanism pure and simple did.

Dr. Roberts said that compression alone had acted well in some cases in his experience, notably in one case of infantile convulsions. An immediate subsidence of struggling had followed gentle digital compression of the carotids. Of course, further practical tests were necessary to substantiate the reader's claims.

Dr. Seguin saw no theoretical flaw in the method, and thought it deserved to be tried. Ophthalmoscopic examination might decide whether, and to what extent cerebral circulation could be influenced by it.

Dr. Berg remarked that it seemed doubtful whether the sympathetic could be galvanized through the integument. He had failed to observe dilatation of the pupil, after using the current for fifteen minutes over the sympathetic.

Dr. Corning replied that he had seen dilatation.

Dr. Roberts believed that the action of electricity might penetrate deeply, just as counter-irritation produced other than merely superficial effects.

Dr. Webster stated that he had been unable to discover any change in the retinal circulation during compression, but perhaps this was owing to imperfections in the apparatus at the time of experimenting. He added with regard to the relation between ocular and cerebral circulation, that hyperæmia or anæmia of the eye might occur independently of a similar condition in the brain. Strong carotid compression should certainly affect retinal circulation in a visible way.

A New Journal.—The *Eco Cientifico de las Villas* is a journal published semi-monthly in Sagua la Grande, Cuba, by Dr. Agustin W. Reyes. It is devoted to medicine, agriculture, and general literature. The original articles on medical subjects are interesting and well written, and the selections from foreign periodicals are made with good judgment. The journal has just completed its first volume, and we congratulate the editor on his success, and wish his undertaking the long life and prosperity which it so well deserves.

Correspondence.

OUR VIENNA LETTER.

(From our Special Correspondent.)

IODOFORM POISONING AND THE USE OF IODOFORM IN PROFESSOR BILLROTH'S CLINIC—OBSTETRIC OPERATIONS —THE DISCOVERER OF COCAINE IN ANOTHER RÔLE.

Vienna, January 10, 1885.

Professor Billroth in a recent lecture spoke of iodoform as the best and most useful antiseptic drug. He preferred it to the hydrargyri bichloride solution—which is at present the antiseptic in use in Germany and England—for the following reasons: The latter discolored the instruments and destroyed their polish, and Professor Billroth takes the utmost care of his instruments. By constant use of the bichloride, even in weak solutions, the hands of the operator become soon unfit for delicate operations, where a nice sense of touch is required. The skin on the hands, and especially about the tips of the fingers, is hardened cracked, fissured, and sore. But the principal objection of Professor Billroth was, that many cases of mercurial poisoning had occurred with the use of this antiseptic. Some of these cases had resulted fatally. With iodoform and carbolic acid solutions none of these objective features were present. Iodoform properly used caused absolutely no severe symptoms. Formerly there had been cases of iodoform poisoning; these were divided into two classes, the light cases of poisoning and the severe form. In almost all of the operative cases in the surgical wards, within twenty-four hours a yellow color appeared in the urine, a slight odor of iodoform in the breath, and a faint taste of iodoform was present. These symptoms soon passed off, and were not of any importance. The lighter set of cases of poisoning were characterized by gastric symptoms, increase of the above symptoms, slight nausea, and vomiting and headache. This was the form of poisoning which presented at times in the clinic, usually after wounds of extensive surface which had to granulate, or in wounds about the mouth or face. These cases were treated symptomatically, and recovered in two or three days without any further trouble. The severe form of iodoform poisoning usually proves fatal. According to the experience in the surgical wards here, it need never occur; only two such cases have happened, and these early in the use of iodoform for antisepsis. One of these was a child which was supposed to have meningitis, but on autopsy no trace of meningitis could be found. As the patient was having a wound of some size dressed daily with powdered iodoform, this was set down as a case of poisoning from the use of the drug. The other case was a woman who had had a large tumor removed from the breast, leaving an extensive raw surface; to this surface, by mistake of the nurse, fresh quantities of iodoform gauze were applied repeatedly within twenty-four hours. The patient became rapidly delirious, there was strong odor to the breath, high fever, vomiting, bloody diarrhœa, and the ordinary symptoms of meningitis, followed by death. Many of the cases which had been recorded as iodoform poisoning were thought to be cases of acute septicæmia where the antiseptic precautions had been imperfect, although iodoform had been used.

The preparations of iodoform in use in the service of Professor Billroth, are the following: 1, The powder, used in places where the gauze is impracticable, as in the pharynx, or in wounds of the soft or hard palate; 2, the gauze, of three kinds; the ordinary gauze for general dressing purposes, containing from ten to twenty per cent. of iodoform; the iodoform gauze with colophonium, used about the mouth and where there is parenchymatous bleeding; and a third variety of gauze with tannin and iodoform, used where there is profuse bleeding, as in operations about the face and genitals; 3, an emulsion with glycerine, containing about twenty per cent. of iodo-

form, and used as an injection after the evacuation of pus in cold abscesses, in empyema, etc.; 4, iodoform with collodion, used in small superficial wounds, ulcers, etc.; 5, iodoform pencils, of different sizes, for insertion into sinuses, urethra, etc., containing about seventy-five per cent.; 6, iodoform vaseline, twenty to forty per cent.

The powder is only used when the gauze cannot be, and not in large quantities. The gauze must come everywhere in contact with the fresh surface, if it is a wound whose edges are not brought together; over this first layer of gauze is heaped layer upon layer of the same material; over this absorbent cotton and the ordinary bandages. This dressing is always to be removed within the first twenty-four hours after the operation where there was much bleeding, or in operations of considerable size, and entirely new dressings applied in the same manner. This second dressing is not to be changed in from eight to fourteen days. This rule is especially insisted upon, particularly in wounds about the mouth. Repeated changing of the dressings, with the use of fresh gauze, is the chief cause of iodoform poisoning. In wounds which are to heal by granulation, very light compression is made. Before applying any dressing, the wound and the parts surrounding it are always thoroughly irrigated with a one per cent. solution of carbolic acid. With these precautions, in spite of what would seem to the American surgeon the immoderate use of iodoform, there has not been a single severe case of iodoform poisoning in Professor Billroth's service.

In the obstetrical service, during the holidays, several capital operations have been made. Two craniotomies, and two Cæsarean sections, within a few days of each other. The former resulted successfully. In the latter two, both mothers died, and one child. In one case the patient was in a comatose condition when the operation was begun, and died in a few hours. In the other case, the conditions were all favorable; labor had just begun, and the mother's condition and the fœtal heart were both good. The patient had a rachitic pelvis with a true conjugate of under 5 ctm. The Porro operation was made by Professor Carl Braun, and lasted only twenty-five minutes; the child was removed alive. The operation was made under the use of the bichloride of mercury solution, and iodoform as antisepsis. The patient did well until the eighth day, without a rise of temperature. On the eighth day the stitches were removed, the abdominal wound having evidently united. That evening the patient had a severe attack of coughing, during which the wound reopened and a portion of the bowel protruded. This was immediately replaced and new stitches put in, but the patient died of peritonitis on the tenth day after the operation.

Another fatal result in the birth wards, last week, was a case of placenta previa with central implantation. The patient came into the hospital in labor, almost pulseless at the wrist and with cold extremities. Version and delivery of the child, which was dead, was done immediately, followed by transfusion, but the patient died six hours after delivery.

Dr. Kohler, the discoverer of the anæsthetic properties of cocaine, has brought himself into notoriety again. He was the challenged party in a duel which he fought with one of his colleagues, an assistant in Professor Billroth's clinic, and he used his opponent so badly that it is considered quite possible that he may not recover. The duel was said to have been fought by permission of the director-in chief of the hospital.

MARTIN'S METHOD OF TREATMENT OF SYNOVITIS, ESPECIALLY OF THE KNEE-JOINT.

To the Editor of The Medical Record.

Sir: The announcement of the surgical uses, other than hæmostatic, of the pure rubber bandage, was made to the American Medical Association by my father, Dr. Henry A. Martin, at Chicago, in 1877. Since that time the almost constant reports of new applications of its use, in very varied requirements of surgery, and its universal adoption in all parts of the world, have given it a most prominent position among the appliances of modern surgery. Although in the minds of many physicians the use of the bandage is associated chiefly with the treatment of varicose veins, eczema, and chronic ulcer of the leg—yet the greatest benefit is to be obtained from it in many other affections, and this is true in the highest degree of inflammations of, and effusions into, the joints:—notably the varied degrees of synovitis of the knee.

At the International Medical Congress at London, in 1881, my father presented a concise paper giving his special investigations in regard to this subject. This paper is published in the Transactions of the Congress. Since his return, he has devoted himself very earnestly to following out the method of treatment which he advocated there, and it was his intention to lay the whole matter before the American Medical Association at the coming meeting, next summer. Owing to his sudden death, this will be impossible, but as I have kept the records of his cases, and have operated on and had charge of many of them, I may be permitted to set down briefly some of the results that have been arrived at.

During the past thirty-one years over four hundred cases of synovitis of the knee and its sequelæ, of every form and degree of severity, in every variety of diathesis and complication, however chronic or acute, have been treated by the use of the pure rubber or "Martin" bandage—applied to the limb from the foot to above the knee. The joint is previously strapped from three inches above to a corresponding point below the patella, with non-irritating rubber plaster. This strapping is not applied for the ordinary reasons, but to obviate, or at least mitigate, a troublesome chafing of the skin in the popliteal space, from walking exercise while the bandage is on the limb. One such strapping will remain *in situ* for four or five weeks, and in a very large proportion of cases has not to be repeated. The plaster, however, must be perfectly non-irritating. The bandage should be applied as tightly as the patient can wear it with comfort. There is no danger to the circulation by following this rule, as no dangerous constriction of the limb could be endured without pain and discomfort. The bandage thus applied should be worn in general for from four to six weeks, according to the severity of the case, day and night; and, after that, during the day only, or while in the upright position, for from four to eight weeks longer. Many patients prefer to wear them a good deal longer, to prevent any possible return of trouble, but this is in general not at all necessary.

When the bandages are thus applied, great comfort and support are at once experienced, and with these much increased capacity to use the joint. Very soon it becomes evident that absorption of effused fluid, and of the interstitial deposits in the tissues of the synovial sac, and of the other tissues about the joint, is going on; and, in a space of time too short to be credible to those who have not accurately pursued the practice, and carefully and repeatedly observed the fact, the enlarged and weakened articulation is restored to the normal size, and, if not immediately to its original strength, to a far greater capacity for use, and eventually to a perfect restoration in all respects.

In cases where the amount of fluid effusion within the sac is small, or where the thickening of the sac is the principal element of the case, these results may be always looked for with certainty and rapidity. Sometimes, however, when the amount of fluid effusion is very large, the use of the bandage *alone* (although of the greatest value as a palliative, by strengthening the joint, and permitting painless use of the limb) will produce *complete* absorption of the fluid very slowly, if at all. The existence of these exceptionally obstinate cases induced my father, some twelve years ago, to add to the use of the bandage a preceding thorough aspiration of the sac, all the other points of treatment being exactly as before described. This

was done at first only in exceptionally obstinate cases, in which the effusion within the synovial sac was large, but the operation was gradually found to be entirely free from danger, and latterly aspiration has been practised in all cases in which, being chronic, the synovial effusion is of any considerable amount, and even in the most acute cases in which rapid effusion produces great distention and consequent pain. The results of my father's experience are summed up in the following statements :

1. In the last twelve years over two hundred cases of synovitis of the knee, and its sequelæ, have been treated by aspiration with a single strapping of the joint, and subsequent use of the bandage.

2. In these cases the knee-joint has been punctured over four hundred times.

3. In all these cases, with the exception of a very few, and these only in the early stages of treatment, the patient was not only permitted, but obliged to take a daily and considerable amount of walking exercise.

4. In not a single instance has there been failure of absolute and entire cure, requiring, in one case, seventeen weeks, but in no other more than eleven weeks.

5. Although no antiseptic measure, beyond perfect cleanliness of the aspirating needle, was employed, in not one instance has any ill symptom followed the operation. When the needle is withdrawn, the puncture is at once covered securely with adhesive plaster.

Sir Benjamin Brodie long ago declared most emphatically, that when the synovial sac is distended with fluid, it can be punctured, and the effusion drawn off with perfect safety. He does not by any means regard this as a help in treatment, however, as he says the fluid will accumulate again, and in a few hours the joint will be as much distended as before. The originality and value of my father's method of treatment lies in successfully demonstrating the fact that thorough aspiration of the knee-joint, followed by proper use of the rubber bandage, gives us a complete and satisfactory method of cure in even the worst cases of synovitis. By the firm and equable pressure of the rubber bandage, the re-accumulation of fluid is checked. If there is any return of the fluid at all, it is in very much diminished quantity, and a second, or perhaps in severe cases a third, aspiration of the joint is all that is ever required. One great advantage of it is to explode the idea that perfect rest of the joint is the only way to hope for a cure. The patient is emphatically *not* to be confined to bed, or, worse still, to a fixed splint. When the joint is strengthened by a properly applied rubber bandage, exercise is a very great and important adjunct in the treatment. This very day I have visited a lady who passed last summer in Switzerland. While there, she was attacked with acute synovitis of the left knee, with large amount of effusion into the sac. She was kept in bed, with the limb placed on a fixed splint and continually poulticed. After sweltering through the hot weather with the limb swathed in many thicknesses of cotton wadding, at the expiration of two months the splint was removed, and—she has come home with a joint almost immovable! I am sure that had this case been treated by prompt aspiration of the sac, and the proper use of the rubber bandage, a perfect and rapid cure would have resulted without a week's confinement of the patient to her bed.

I trust that other surgeons will have employed this method of treatment in a sufficient number of cases, to make a thorough discussion of it possible at the next meeting of the American Medical Association.

FRANCIS C. MARTIN, M.D.

ROXBURY, MASS., December 22, 1884.

CANCER A FREQUENT CAUSE OF DEATH IN HORSES.—The *Indian Medical Gazette* says: As in England, *melanotic cancer* is an ordinary cause of death in Bengal among gray and white horses. We can scarcely drive through Calcutta without seeing animals having the characteristic globular tumors beneath the skin.

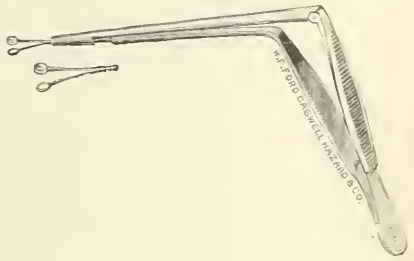
New Instruments.

A FENESTRATED CARTILAGE FORCEPS.

BY WILLIAM C. JARVIS, M.D.,

NEW YORK.

I HAVE successfully employed the little instrument, represented in the accompanying illustration, for more than two years, to facilitate the removal of deviations of the



cartilaginous septum narium. Briefly described, the cutting blades may be compared in shape and action to an ordinary ticket punch. The blades at rest are always apart, being kept so by the resiliency of their steel stems.

The handle of the instrument is bent at an angle suitable for simultaneously viewing and operating within the nostrils. A slight pressure of the thumb exerted against the handle, forces forward a metallic tube, which firmly clasps the stems supporting the cutting blades, and thus drags the ring-knives together. In this manner small pieces of deviated cartilaginous or hypertrophied tissue can be successively excised until the desired effect is obtained. The instrument may be also employed as a *trimmer* for removing the asperities sometimes remaining after the excision of large sections of deflected septal cartilage by means of my transfixion needle and écraseur. It is hardly necessary to add that the procedure is absolutely painless when good cocaine is properly applied; the hemorrhage also is insignificant. Mr. W. F. Ford is the manufacturer of this novel device.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 25, 1885, to January 31, 1885.

WEBSTER, WARREN, Major and Surgeon. Granted leave of absence for one year on surgeon's certificate of disability. S. O. 20, A. G. O., January 24, 1885.

TAYLOR, B. D., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect between March 15 and April 1, 1885; permission to leave Department limits. S. O. 10, Department of Texas, January 26, 1885.

KEAN, J. R., First Lieutenant and Assistant Surgeon. Ordered for duty in Department of Missouri. S. O. 23, A. G. O., January 28, 1885.

PROMOTIONS.

SUMMERS, JOHN E., Lieutenant-Colonel and Surgeon. To be Surgeon, with rank of Colonel, January 9, 1885.

SMITH, JOS. R., Major and Surgeon. To be Surgeon, with rank of Lieutenant-Colonel, January 9, 1885.

KOERPER, EGON A., Captain and Assistant Surgeon. To be Surgeon, with rank of Major, January 9, 1885.

APPOINTMENT.

RAYMOND, HENRY I. To be Assistant-Surgeon with rank of First Lieutenant, January 12, 1885.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 31, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
January 24, 1885.....	3	12	78	7	130	54	0	0
January 31, 1885.....	2	12	80	5	157	48	0	0
Deaths.

January 31, 1885.....	0	6	11	5	36	24	0	0

The Boy and the Bone-Setter.—Speaking of bone-setters recalls a good story which occurred in the North of Scotland, where one of them had risen to great fame and no small fortune by his skill. A country lad residing a few miles off had got his leg hurt at one of the local factories, and had been treated for some time by the local medical man without any good result. His mother, who had great faith in the neighboring bone-setter, wanted the lad to go to him, which he declined, preferring, as he said, the "reg'lar faculty." Eventually, however, his mother's persuasions prevailed, and he agreed to allow himself to be taken to see Daniel R——, the bone-setter. A bed for the invalid was extemporized on a cart, and, accompanied by his anxious mother, he was after a rather painful journey taken to the town where the bone-setter resided. The leg was duly examined, and it was found necessary to haul it very severely, in order, as the bone-setter said, "to get the bone in." The lad was liberal with his screams while this was going on, but eventually the bone was "got in," and he was told to go home and in a few days he would be all right and fit for his work. He was lifted upon the cart again, and, with his mother seated beside him, set off for home. "Didn't Danny do the thing well?" said the joyous old lady. "Yes, he did, mother," said the lad, "but I was na sic a fool as to gie him the sair leg!" The "reg'lar faculty" will, we have no doubt, appreciate the story.—*Whitehall Review.*

An Inopportune Dislocation of the Jaw is mentioned in a recent issue of the *Union Médicale*. It seems that during the performance of a wedding ceremony the bride sneezed so violently as to dislocate her jaw at the critical moment when she should have pronounced the solemn "oui." As she was unable to articulate the word, it was found necessary for the whole party to repair to a surgeon before the ceremony could be completed.

Bichloride of Mercury vs. Muriate of Iron in Diphtheria.—Muriate of iron blackens and injures the teeth, and is not as useful in diphtheria as syringing with simple salt and water or bichloride of mercury. All experimenters agree in placing this in the front rank as a germicide and antiseptic agent. One to 40,000 prevents the development of septic germs, and but little less is required for the most virulent pus and bacteria. One to 10,000 destroys the vitality of bacteria in spoiled beef tea. It requires only 1 to 5,000 to kill the germs of malignant pustule. It forms the basis of the modern successful treatment of malignant diphtheria. The throat is frequently syringed, or irrigated, with a weak solution, and exceedingly small powders of it are given dry upon the tongue. It is the great adjunct of quinine and arsenic in typho-malarial and civic-malarial fevers. In septicæmic blood-poisoning it aids the action of food, alcohol, and quinine. But where the labors of scientists end there those of practical physicians begin. One bacterium will produce 16,500,000 in twenty-four hours, and 281,500,000,000 in two days. In septicæmic blood-poisoning, counting twelve pounds of blood in a man weighing one hundred and sixty pounds, there will be 70,000 grains of blood, counting 5,760 grains to the pound, troy or apothecaries' weight, to disinfect. It will require at least three and a half grains of corrosive sublimate to do this, and we can only give from one-twelfth to one-sixteenth of a grain three times a day. As it will require six or eight days to get in all the corrosive sublimate required, we have to depend upon the common remedies, viz., food, alcohol, and quinine to keep the patient alive in the meantime. The disease goes on increasing, or not lessening; remedies seem powerless, but succeed in the end.—*Medicus.*

The "Physician's Certificates" employed frequently in courts occasionally subject their writers to censure or criticism. This is not lessened when they bear internal evidence of faulty preparation. In a recent trial, the prisoner, in an affidavit, was described as "confallesant" but had been "irratable!" We know a practitioner who invariably speaks of a lying-in case as "a case of *midriffery.*" Attention to the small matters of spelling and pronunciation will frequently save the profession from public humiliation in the hands of critics through the writing or speaking ass.

The Dispensary Evil again and a Remedy.—"*Caritas Vera*" sends a letter upon this subject, which we are unable to publish in full. Referring to the present extent of medical charity in this city he says: "At fourteen of the chief dispensaries of New York City, there were treated gratuitously in 1883 no less than 230,000 persons, or considerably more than one hundred to each legalized practitioner of medicine in the city. This does not take into consideration the innumerable smaller dispensaries, out-door departments, etc., the vast number annually treated in the wards of our public hospitals, or the charity patients which every physician must perforce meet with in his private practice. If one is to judge from these figures alone he must inevitably come to the conclusion that New York is the most poverty-stricken city on the footstool. Besides, new dispensaries are looming up on every hand, and verily it seems that they will soon dispute the supremacy of apothecary shops and refreshment saloons in point of numbers. In making a professional call within the past twenty-four hours, the writer was obliged to pass, on his way to the patient's residence, the doors of no less than five of these institutions, and within the immediate neighborhood of two others!" The house-surgeons and clerks at dispensaries do not make careful enough inquiries as to the status of applicants for relief, being mainly anxious to increase the size of the classes. Herein, our correspondent says, lies a remedy. "If each and every patient applying for relief at our dispensaries were given to understand that such institutions were designed only for the poor and destitute, and were required to state clearly and positively that he was in need of public aid, the writer apprehends that there would soon be considerably more sitting-room on our overflowing dispensary benches. If a dispensary physician sees fit to question patients whose poverty he has reason to doubt, as to their ability to pay, he will find much similarity in their replies. In a number of cases in which the writer has ventured to make inquiries of this nature, he has usually met with replies about like this: 'Why Mrs. H—— has been coming here for several months, and she is much better off than I am;' or this: 'Oh, I went to see a private doctor, but he didn't seem to understand my case, so I came here to see a specialist." A few stated that they were unacquainted with a private practitioner. But a very small number, indeed, admitted that they considered themselves objects of charity, and some even flounced out of the dispensary in high dudgeon on such occasions."

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 27, No. 7 NEW YORK, FEBRUARY 14, 1885 Whole No. 745

Original Lectures.

INAUGURAL ADDRESS,

DELIVERED BEFORE THE NEW YORK ACADEMY OF MEDICINE.

BY A. JACOBI, M.D.,

PRESIDENT OF THE ACADEMY.

IT has been my privilege to enjoy many professional honors. Whatever favors my colleagues of both city and State could ever dispose of, they have liberally conferred on me at different times. To-night I am called upon to acknowledge my indebtedness and express my thanks to you for an extraordinary proof of your consideration and confidence. I do so from the depths of my heart, my pride in my elevation to the presidency of the New York Academy of Medicine being checked only by the overwhelming sense of the grave responsibility incurred.

In regard to the two highest positions the profession of the city has ever placed me in, I have been both fortunate and embarrassed. For when, some fifteen years ago, I took the chair in the Medical Society of the County of New York, my predecessors were Edmund R. Peaslee and George T. Elliott. The former was erudite, wise, a celebrated specialist, a renowned writer of great weight and force. The latter was bright, quick, versatile, as eloquent as his predecessor, conversant with the literature of his profession, also a good writer, and universally admired and loved for his pleasing manner and thoroughly gracious bearing. The difficulty of presiding after such men was relieved by but one all-important circumstance, which was this, that they had raised the Society to a flourishing condition such as had never existed before.

Now, as concerns the presidency in this Academy of Medicine, I believe I am in nearly the same position. If I were more eloquent I should try to do justice to the president of so many years, in recalling his services in the interest of the literature of medicine, of the standing of the profession at large, and of the development of this Academy. To say that the medical world knows him well, that we, the profession of the city, and the members of the Academy, are under great and respectful obligation to him for his untiring care and energy, his enduring patience, his kindness and urbanity, and his uniform success in conducting the affairs of the Academy, is but an incompetent expression of my feelings. Personally, I add my extreme gratification at the fact that it was under his guidance and supervision that the Academy could overcome such dangers and strifes as I hope these walls will never behold again. As they, however, are things of the past, I hope I shall have nothing to do but to preside over harmonious scientific meetings only, such as were contemplated when the Academy was founded. It will be my ambition and pride to contribute to its success as much as I can, hoping, at the same time, that your expectations will not be measured by Dr. Barker's eulogistic remarks, which I should be glad to deserve. In regard to them I will only say that I believe they were made on the principle and for the reason, that it is wise to stimulate ambition into powerful efforts for the accomplishment of ends by praising beforehand. The members present I beg again to receive my thanks, my promises, and my request that every one may consider the interests of this Academy under his personal charge. It will then be an easy task not only to preserve its high character, but in the course of time make it the largest and most influential scientific institution in the country.

How this can be accomplished has engaged my thoughts more than once. For the New York Academy of Medicine has been established for more than one purpose:

First.—The cultivation of the science of medicine.

Second.—The advancement of the character and honor of the profession.

Third.—The elevation of the standard of medical education.

Fourth.—The promotion of public health.

It has not been founded upon the plans of European institutions bearing similar names. The academies of sciences or of medicine in Europe, established for the promotion of the science and art of medicine, are institutions with a limited number of members, who have peculiar claims for such distinction. In them we find the most representative men only. Every one is a specialist in his way, a teacher, a savant; most of them are men of reputations, many are celebrities. They are professors in universities, directors of clinical institutes, independent of pecuniary compulsion to practise medicine, enjoying the leisure required for studies of their own. They are governed in part by rules prescribed by the government, which pays for their services either rendered to a public institution, or to pure science.

Our Academy is a democratic institution. It is not limited in numbers—on the contrary it is desirable that the many respectable physicians should gather round its flag. Like our political community, it looks for its development and success in the co-operation of the competent and cultured masses. Like the Union, it is a voluntary confederation of peers who make their own laws, and obey them because they are of their own making. The members have the same interests, both scientific and professional. There are but very few of us who are not engaged in the practice of medicine. When the Academy was founded, the members were, all of them, general practitioners; specialists there were but few. This has changed much, both study and practice have tried to become more profound by circumscribing and limiting their aims. But all of us are active men, not tied down or given up to study only. Thus we perform less laboratory work than they do in Europe, and write fewer monographs on special subjects. But the number of facts closely observed at the sick-bed or in the examining-room has increased from year to year. In spite of the circumstance that we are all busy men, the literature of medicine in New York and the United States is no longer mostly parasitical, as Oliver Wendell Holmes was justified in complaining during the session of the second meeting of the American Medical Association. Original work has taken the place, in part, of translations and reprints; still all the time the connection between the medical men and the public, the doctor and the patient, has not been severed. This is the peculiar feature of American, as it is of British, medicine. Anglo-Saxon medicine has never forgotten that the aim and end of all medical science is the treatment and healing of the sick, and that every special study is but a means to obtain that end.

Thus our Academy is not to be the centre of a select

few, who speak to the rest of mankind through their writings only, but of all who love their science and live the lives of respectable practitioners. All ought to be members. I have often been told, however, that the large number of societies prevents men from becoming members in the old and large ones. That is so. There is too much division and subdivision. But that is not the fault of the Academy. Under other circumstances the Obstetrical Society might well have been a section of the Academy; the laryngologists, otologists, ophthalmologists, dermatologists, might have their own sections under the auspices of the Academy, though under their own rules, their own officers, and, while doing the same amount of good work, not lose their connection with the main body. The large societies, such as the Academy, or the American Medical Association, or the German Association of Physicians and Naturalists, lose by the secession of important branches and their representatives. The unity of medicine is lost sight of, and the interests of science and the profession are suffering. Instead of one or two, every section of this Academy ought to be flourishing. Let us hope they will. We have been told to-night that there was more than an abundance of papers offered. Our rooms they are welcome to. Though we have to think of some time increasing our facilities, we can still accommodate them, and others besides. Indeed, most of the medical societies of the city would do well to avail themselves of the home the medical profession of the city have found in this hall, and meet here.

The peculiar features of this Academy I have mentioned permit of varied results. The mixture of the best brains of the profession and the modest practitioner is capable of raising the standard of the average professional man far beyond the level of the European medical man, frequently in knowledge, always in industry and ambition and ethics, without interfering with the individual and original labor of the hardest workers and best thinkers. Have we been successful on this side of the Atlantic?

They say we have no John Hunter. All Great Britain, in all its pride, has but one. No Bichat or Laennec. All the glory and elegance of France have but one. No Virchow. All the centuries of toiling and philosophical Germany have produced but one. What we do have, however, is a medical profession with unbiassed minds, clear insight, critical eyes, undaunted industry, and that republican courtesy which recognizes—*suum cuique*—the peculiar advantages and services everywhere, and the democratic tendency of appreciating, and appropriating, the intellectual accomplishments of the globe, and of utilizing them for the practical necessities of the commonwealth.

Besides, we do not live in the back woods, or in the darkness. As long as the Confederation and the Union have been in existence, their medical men have been, to say the least, marching in line. In what the Anglo-Saxons have known and taught, they have both participated and co-operated. Without the counting in of the original American contributions to science, the history of modern medicine would be incomplete indeed. Let Europe boast of their great names: this young community has the heirloom of the great names of Bard, Rush, McDowell, Drake, Beck, and many others of *past* years. Let the history of this Academy be written—and a grateful and gratifying labor it would be—and the array of great names is such as to astonish many of the young men in this room, who unconsciously and unconcernedly toil over the graves on which are inscribed the names of men great in literature, or achievements, or influence, great in mind and character. Let me mention a few of those who have passed away. I have known personally, and conversed and discussed with, John O. Batchelder, George M. Beard, Gunning S. Bedford, Ch. A. Budd, Gurdon Buck, H. D. Bulkley, William H. Van Buren, Freeman J. Bumstead, Henry G. Cox, George T. Elliott, John W. Francis, Edward Delafield, Elisha Harris, Horace Green, Ernst Krackowizer, Valentine Mott, Josiah Clark Nott, Edmund R. Peaslee, Willard Parker, J. Marion Sims, Joseph M. Smith, Alexander H. Stephens, James Stewart, John Watson, Robert Watts, Isaac Wood, James R. Wood. Many of these names are known wherever medicine is taught and practised; some of them will never die. This Academy will always cherish the names of its members who contributed to the glory of universal medicine and the American country.

When I, and those as old as I, knew these men, most of them were in advanced years. At that time the proportion of white heads was very much larger than it is to-day. I venture to say that it was for the good of the Academy that that was so. Neither the political republic nor that of science can thrive without the co-operation of all. At that time the number of older and old men was such as to draw forth sometimes the remark of some class of young men that the Academy was the headquarters of old fogies, and for that reason might be avoided and shunned. Much has been changed in this respect. Curly heads and young faces are plentiful, a good sign indeed for the energy and activeness of the growing generation. Many white beards, however, and bald heads have commenced to stay away for years, a proof indeed of the increased claim on their time and strength, but we fear also, now and then, of listlessness and indifference.

This ought not to be so. Neither in politics nor in science does age extinguish citizenship, with its rights and duties. Besides, I know that the best trained young minds are modest enough to admit that they are able and anxious to learn from those whose opportunities extend over a long number of years, and that books, brains, and experience are a greater power than books, brains, and inexperience.

These remarks I make for the purpose of requesting the older members of the profession not to withhold their presence and aid. Among them are men widely known in both hemispheres. When they write everyone reads, both here and in Europe. Let them not forget that a vast audience is just as anxious to hang on their lips when they either lecture before us, or take part in a discussion. They owe their teaching and their example to the rising generation of our younger brethren. They will teach them both medicine and modesty. May nobody who neglects his own duty toward them and the profession at large accuse a young man of forwardness. Some of them have indeed reaped a good harvest from living up to their duties as citizens of our republic of science. For if there be a fountain of youth for old men, it is the constant mixing and working with the young. The Nestor of our surgeons, whose face we greet with joy in almost every meeting, and whose voice we are delighted in hearing in our discussions, proves better than any preaching the powerlessness of so-called old age.

The hosts of others, general practitioners and surgeons and specialists, whom we like to boast of and to honor, will always be welcomed by all of us, both old and young, to seats in the front ranks. If they will consent, not only our scientific but also our public aims will be more apt to be reached.

For our position is that of the natural advisers in all matters concerning sanitation and health. The larger the number of our members, the more we represent the best minds and all ages in the profession, the more readily the public and its legislators will listen to us. When they know that our advice will be the digest of the best knowledge and the ripe wisdom of the profession, they will not wait until it is forced upon them. In matters of health the two large medical societies of the city ought to be, will be, the authorities. If that be so, it will no longer depend upon a number of ladies only to remove intolerable nuisances from the heart of the city. The simple appeal of the profession will become the protection of the public. The latter will soon learn that it can rely on your knowledge and public spirit, and as it calls on the bar for legal advice, it will consult the medical

profession for sanitary necessities. In this way it will happen that some time the President of the Board of Health will be nominated, or appointed by the profession; that no Board of Education, no Board of Charities will be complete without a prominent medical member; medical bills will pass the Legislature, when backed by the whole power of the profession, without either delay or mutilation; the supervising officers of factories, nurseries, streets, baths, gas-houses, will be physicians; aye, the most improbable thing will happen, which is this: that the public will acknowledge that the government of hospitals ought not to be without medical advisers in their boards. In order, however, to accomplish such results, we must unite our numbers, powers, and influence. The public and legislatures will respect and obey the regular medical profession more eagerly than the advice of individuals or societies. It gives me great pleasure, in this connection, to be able to announce to you that the representatives of the profession of the State agreed but yesterday on a bill to be presented to the Legislature, ordering a Board of State Examiners destined to license the practice of medicine. The unanimity of action in this respect on the part of apparently diverging and conflicting interests is a good omen, in this progressive State, for the growing influence of the medical profession. . Thus far the State Medical Society has done its part of the work nobly; now, may everybody see to it that the Legislature of the State be kept well informed and well advised.

The practical tendency of this Academy corresponds with the peculiar practical nature of the development of medicine in the English-speaking nations from the last century onward. Even the most fragmentary study of that development is of great interest indeed. Altogether, medicine in the eighteenth century exhibits a peculiar character. It is true that knowledge was not widespread, but the heads of the profession were capable, painstaking, searching, cool-headed men, good observers, and excellent describers. There was a large number of good monographs, excellent histories of cases, and fair diagnoses of the general condition of the patient. Local diagnosis, it is true, was mostly out of the question, since no sooner than in the second half of that century Morgagni collected in his illustrious work, "De Causis et Sedibus Morborum," all of the only three thousand post-mortem examinations which had ever been recorded in all ages and countries. Their judgment was sound, their therapeutics—though often exuberant—safe. As the scientific language of most of them was the same, Latin, their spirit was not local nor national. The same class of men were found in Germany and the British possessions; also in Holland and France. In the former we meet the names of Werlhoff, R. A. Vogel, Zimmermann, Lentin, Van Swieten, J. P. Frank. There was also Auenbrugger, who ought not to have been so readily forgotten. In Great Britain there were Mead, Huxham, Fothergill, Pringle, Heberden, Monroe, Home, Cullen, there was that giant John Hunter. In America we had Bard and Rush. In France, Levret. In Holland, at an early date, Boerhaave. The only fanatical theorist of all the English writers was John Brown; the only obscurist, who ought to have had a place in Germany between 1800 and 1840, was Robert Jones, with his "Inquiry into the State of Medicine on the Principles of Inductive Philosophy" (1782). When Broussais reigned supreme in France, his doctrines were welcomed by a great many in England. But the Anglo-Saxon mind is not easily drawn away by theories, and there is after all more solid work in Broussais than wanton theory only. Thus the English literature of the early part of this century teems with good observations and monographs by many more than those I here mention—Travers, Williams, Crawford, Astley Cooper, Brodie, Bell, Abercrombie, Cheyne, Pitcairn, Bright, Hope, and Carswell.

Of French names I have mentioned but one.

The redemption of France, after a century of almost unparalleled corruption and misery, begins with its great Revolution. Never before did fate grant to an unhappy nation a larger number of great spirits, both in politics and science. The faint impression the freer institutions of the British Island made on French literature would not have influenced the development of the country for centuries to the same extent as did the necessities of the population. In the history of political and mental development changes more or less sudden or gradual appear to be the rule; rise and decline change off, as the fertility and sterility of a corn-field. The fertility of France lasted a long time. While the greatest man in its political world could not do better than spread all over Europe part of the results of the French Revolution through violence and murder, a young scientist revolutionized medical science by genius and hard work. That is what Bichat did when he studied the physiology and pathology of the organic tissues. Since that period, France has marched at the head of medical science for about half a century. Pinel, Corvisart, Cruveilhier, Biett, Cazenave, Gibert, Laennec, Ricord, Civiale, Guérin, Guislain, Baillarger, Leuret, Longet, Guersant, Taupin, Valleix, Legendre, Dupuytren, Trousseau, Rilliet, Barthez, Durant-Fardel, Orfila, Louis, Broussais, Piorry, what a host of illustrious names, and by far not the only ones who will recall the glory of the French nation when there will be no longer a political France. It is true that a decline has set in. The number of really great men in modern French medicine is but limited. Charcot's name overshadows the reputations of all others, and it appears to me will live for centuries. May be also that Pasteur will be recognized as a fixed star in the scientific sky if he will succeed in divesting himself of the doubtful attributes of polemical tendencies.

After Bichat there are three French names connected with the history of medical sciences in all countries. Laennec's revolution of diagnosis by percussion and auscultation, is not any the less important and precious because Auenbrugger had worked in the same field more than half a century previously, for no other purpose but complete oblivion. Magendie's experimental physiology and pharmacology has benefited all mankind. His is the introduction of alkaloids, such as quinine, veratrine, strychnine, piperine, morphine, emetine—his the successful admission of bromine and iodine into practical therapeutics. Finally Broussais, by overthrowing ontologies—though he created one of his own—by localizing disease, by urging prevention and abortive treatment, by studying the anatomical lesions of pathological processes, has substituted a method of anatomical thought in diagnosis for the merely clinical and empirical observation of the sick, and thus been the intellectual author of that method of medical knowledge and reasoning which is best known by the name of the Vienna school. I shall have to consider its representatives shortly, with all its virtues and faults, both of which were learned and loaned from the illustrious Frenchman. For not only did he convey to them his anatomical way of thinking, but he also taught them to be satisfied with coarse local anatomical lesions, and with a nominal diagnosis, adding the assurance that those lesions must lead to death; that indeed the case is either getting well spontaneously, or is absolutely hopeless, and that a treatment of any kind is powerless.

The parallelism of political and scientific conditions which strikes us so admirably in the history of French development after the impulse given by the Revolution, is sadly illustrated by poor Germany. The country poor and forlorn, divided in hundreds of shreds, large and small, tyrannized and robbed by hundreds of dukes and bishops, and princelings of all sorts, every one the inferior in mind, but the emulating admirer of the tendencies of that despotic Frederick the Second of Prussia, in whom it requires the equally despotic soul of a Carlyle to find nothing but admirable traits; that country had, about the end of the eighteenth century, one representative in medicine corresponding with the character of the time.

Hufeland was a fair observer, a copious writer, an influential man, but weak and accessible to everybody and everything. It was he who admitted the first Hahnemannian gospels to his journal, and who was of the wise opinion that there may be something good in everything. Then came the French, and whipped the Germans out of political existence.. Then the wars which expelled the French, bloody, costly, and short, aroused a peculiar romantic fanaticism which pervaded the whole literature of a short decade, and could but have an unfavorable influence on science. Then came decennia of brutal political reaction and suppression, the scanty means of the nation being spent on police, military, and dungeons, in which the flower of the country, and particularly of the universities, was incarcerated. During that time German thought had no place in terrestrial parts; even before that time Schiller had proclaimed man "free though he wore chains." This sort of freedom the Germans utilized to become transcendentalists. The principal method of studying nature was imagination. Even Kant, the mathematical thinker, had taught them the art of construing things *à priori*. Then came Schelling with his system of natural philosophy, and Hegel, who wrote twenty big volumes, and is reported to have said on his death-bed, that in all his life he had but one pupil who understood him, and that one did not know anything about him. Under the influence of these philosophical absurdities no medical science could thrive. That was the time of animal magnetism and granioscopical humbug.

In such a condition of universal intellectual semi-paralysis and revelry in big words and clouded sensations of all kinds, combined with the insensate and murderous character of therapeutics, it was natural that homœopathy could thrive, with its axioms, that disease was an enemy from without, the result of psora or of medicines; that nature was an enemy of man, that nature will not cure a disease but a medicine will; that no medicine will cure which can be shown by any physical or chemical analysis to still exist; that its dynamical power increases with its attenuation and annihilation. That was the time in which one of the great lights of German medicine defined inflammation as the condition in which the "electrical essence (or part) is affected in the dimensions." Marcus never said that he understood that himself. At that time the medical literature of Germany was full of such philosophizing nonsense; full of contempt of the unphilosophical foreign countries; of Bright, with his British coarseness in studying nature as it was; of Laennec, whose percussion and auscultation were declared to be immoral and irreligious. My beloved teacher, Professor Fred Nasse, though all his life a believer in and author on animal magnetism, was one of the first to utilize Laennec's great innovation and the lessons of foreign teaching. Even Schoenlein, though it was he through whose influence young Virchow, after he had been expelled from Berlin for his liberal political views, was called to Würtzburg to teach pathological anatomy, could not free himself from the influence of philosophical doctrines. At that time the science of therapeutics consisted indeed in nothing but empty words, its practice in a great part to the traditional blood-letting, salivation, and purging. Thus it was that the fanatical hydropathists, and the adversaries of vaccination could obtain such rare opportunities and successes; thus that, but forty years ago, Rademacher could divide all ailments into saltpetre. copper, and iron diseases, by reason of the remedies of which each cured one-third of all the ailments of German kind.

Schoenlein and Liebig having prepared the medical minds, and the influence of foreign literatures being gradually felt in Germany and Austria, it so happened that Vienna had in its faculty of medicine quite an array of medical genius. Rokitansky, Skoda, Hebra, have long reigned supreme. Broussais' doctrines, good and bad, were readily accepted; his ontological gastro-enteritis was replaced by Rokitansky's doctrine of the crases of the blood, thus re-establishing the old humoral theory on an apparently firmer foundation. In Rokitansky's opinion the anatomical changes were the only thing in medicine worth knowing. Skoda, for some time, experimented carelessly and unsuccessfully with remedies; his ill-success and Rokitansky's teaching confirmed the nihilism of Broussais, against which Laennec protested in France, and made the expectative treatment and the nihilistic faith the gospel of German practice.

> "This was the medicine—the patients' woes soon ended,
> And none demanded: Who got well?
> Thus we, our hellish boluses compounding,
> Among these vales and hills surrounding,
> Worse than the pestilence have passed.
> Thousands were done to death from poison of my giving;.
> And I must hear by all the living
> The shameless murderers praised at last."

But in Goethe's "Faust" this is said by an incorrigible philosophical roué, who is ready to give himself up to the devil, and in Germany it had the result that the public, who have a right to desire to be cured when they fall sick, preferred the homœopathic pill-box to the pathologist's post-mortem case.

Not long after, Oppolzer, whose name ought to be blessed forever in Prague, Leipzic, and Vienna, began his influential career. In him Germany possessed its first great physician in this century, who knew pathological anatomy perfectly, was a thorough diagnostician, a humane physician and amiable teacher, who recognized the social, scientific, and humane duties of the practitioner, abhorred preconceived ideas and *à priori* constructions, acknowledged principles and facts only, and no duty but to find the truth.

It was about that time that Rudolf Virchow commenced to revolutionize medicine. Modern medical science owes its solid foundation and elaboration to him and his followers. The book of medicine of to-day, and, I trust, of the future, bears the imprint of his genius on every page. We all have read, and admired, and praised, knowing that when we readily place Germany in the first rank of the medical world to-day, the name of Virchow is in every mind, on every lip. This brief sketch cannot do him justice, nor do I desire to elaborate a theme with which every one is familiar. But one remark I cannot suppress, viz.: that he is not only great in his revolutionary discoveries and innovations, but in his self-denying conservatism also. If the bacteriomania of modern time has not been accepted uniformly as the universal gospel of modern pathology, if thoughtful hesitation and healthy criticism is still heard above the noisy waves of the seas of all-explaining and all-saving theories which claim to have given, at last, an absolutely solid base to etiology and pathology, that merit again belongs to a great extent to Virchow. I speak of it here because I hope that this Academy may be able to contribute to the solution of questions of great import, by original studies and discoveries.

For there was lately a time, or rather we still live in that time, when a single series of discoveries lays claim to having changed the aspect of pathology at one stroke, and solved all problems. You know I speak of bacteriology. In America also, all of those who cannot judge of the question by their own investigations, that is, the practitioners, either general or special, have readily accepted the new gospel with but few exceptions. The new theories that infectious and zymotic diseases have each their own bacillus, are so pleasant and promised to be so fruitful that it required some courage to critically resist the flood. On the other hand, those amongst us who have a right by their own researches and special knowledge to be heard, have hesitated to accept the results of microscopical, actual or alleged, discoveries as the sole explanation of everything infectious and zymotic. Amongst them I shall only name Wood and Formad, and Sternberg. Into the merits of the case, and the weighing of reasons I cannot go this evening, but it has appeared to

me that it would be well to direct the attention of the Academy to that subject as one greatly deserving of its attention.

To me, while I readily acknowledge a valuable increase of pathological knowledge, and the fact that the spreading of some diseases at least, slow, and gradual, and regular, seems to prove the multiplication of cases of disease by the regular multiplying of its causes, it has always appeared that purely bacteric etiology has too often begged the question, and that the answer to the question, whether organic or chemical poisons are the main causes of infectious diseases, has, by no means, been satisfactorily given. In the course of the last dozen years organic chemistry has made as rapid strides as has microscopy. Cadaveric poisons, ptomaines, have been discovered in great numbers. Most of them are very destructive. Sudden deaths from zymotic and infectious diseases resemble much those produced by these poisons. That the stings of insects or the poison engendered in putrid corpses lead to speedy destruction has always been known. The symptoms are exactly like those produced by many known poisons. Forensic medicine has a great many instances already in which it could be proven that the poison extracted from the body of the dead was not a vegetable agent, introduced during life, but the cadaveric poison. Count Gibbone was said to have been murdered with delphinine. Professor Selmi proved that what was claimed to be that vegetable poison was cadaveric. In another case he saved the life of a suspected person by proving that it was not morphine, but a ptomaine which was found in the body. Besides the poisons named there is strychnine, colchicine, atropine, coniine, woorara, nicotine, veratrine, hyoscyamine, narceline, the symptoms and chemical reaction of which are the same, or almost so, as the cadaveric poisons. Lecithine is found in putrid fish; a very dangerous chemical poison has been extracted from putrefying Indian corn and rye. Thus it is that many cases of poisoning with cheese, meat, fish, sausage, jelly, and yeast, many of them resembling acute infectious fevers, may find, and indeed have found, their ready explanation.

Brieger found quite a number of different varieties of cadaveric poisons—neuridine, neurine, muscarine, æthylendiamine, gadinine, and others. Many of these destroy life in a short time, and with the symptoms of acute infectious diseases. These poisons are found, in many instances, in the fresh dead body, not in that one which has undergone complete putrefaction. The results of putrefaction will, after a while, change entirely and become rather wholesome than injurious. Many years ago, Salkowski examined a vessel full of ascitic fluid, which he knew to be in utter putrefaction when he last inspected it. Not only was there no putrefaction any more, but, on the contrary, chemical decomposition had formed phenol. Thus putrefaction had worked its own destruction and antidote. The inference, then, is that a poison, even in the course of the same disease, may not always be found.[1]

Ptomaines are often met with in the presence of bacteria. Is it the latter which produce them? Do they so decompose the albumen of the tissue that a ptomaine must or can develop? Or is it their own vital change which produces it? Most modern writers—not chemists—believe it. But if the cause of decomposition of the living or dead be not bacteria, but a chemical poison after all, is it necessary to assume that the poison cannot form except through and with the presence of bacteria? And is the bacterium the only poison? or the only source of the poison?

If deadly poison, such as we know to destroy life suddenly, or almost suddenly, and of such virulence as is reported in what was formerly believed to be legendary only, but which may be historical, will almost invariably originate in the dead body, is it so impossible that it may develop in the still living under certain circumstances? Have we not had enough yet of the monthly instalments of new bacilli which are the invariably correct and positive sources of a disease, and replaced by the next man who comes along? Have we not yet enough of the statements, that, as for instance several bacilli are claimed each to be the only cause of diphtheria, by several observers, that there may be several distinct bacilli every-one of which can produce the same scourge? Is it not just as safe to still presume, that, when several forms of bacilli are believed to be such sole causes, that the real cause is in neither?

Exactly so, neither in one nor in the other, notwithstanding it all appeared settled. For our journals are replete with the very latest authentic bacterium of diphtheria. This time it is neither Klebs nor Eberth, but Loeffler. Reports, discussions, and even editorials carry his name over the world. The very nature of diphtheria is said to be revealed again, as several times before; still, the discoverer admits that there are cases without the bacterium.

The matter is becoming ludicrous. I begin to fear something like the recent rebellion against piano-playing in a large European city. Is not music a godly art, and the piano a blessing to the musician? But the playing of fifty thousand beginners in a large city is a nuisance. When bacterio-microscopy in the hands of beginners becomes noisy like piano-playing—noisy in books, pamphlets, and journals—a gentle protest is permissible. That protest is not meant for the masters who know how to wait and to mature. I do not speak against Robert Koch and his peers, who all of them are more modest than their followers. When the kings build, the cartmen are kept busy—and boisterous.

A dozen years ago the coccus of whooping-cough was said to be discovered. There was no doubt about it. There was whooping-cough, there was a coccus, what was plainer and more conclusive? To cure whooping-cough, nothing is required but to kill the coccus. Quinine will kill a coccus, quinine cures whooping-cough. Since that time there is no more whooping-cough in existence; or, if a case would be malevolent enough to turn up, it could not last longer than until a few whiffs of quinine can reach it. That is ludicrous, is it not? But it was preached like gospel, and it was believed. Many more such have turned up, and will turn up, for coming years to smile at.

There is a peculiar feature in this bacteriomania. Its principal impetus it received in Germany at a time when great changes had taken place in its political and financial affairs. All at once there was an Empire, of which historians so much spoke, youth so much dreamed, romancers so much fabulated. All at once, at the same time and a decade before, an unusual industriousness, commerce, enterprise, and unwonted wealth, and still more expectations than wealth; all at once an influx of five thousand millions of francs, not earned by honest work, but conquered by war, which could not but turn the poor heads and unstable the solid foundations of regular development. From that time dates that lack of safety and steadiness in German financial circles. They have even invented a name for that period of swindling, "gründerthum." Speculation was rife—fortunes were made in a day from nothing but self-assertion and daring and lost as quickly.

The moral and intellectual atmosphere created by these tendencies is never breathed by one class of people only. If self-assertion can make a fortune in finance, why not in science? If a reputation may perhaps be made by a stroke of chance, why not try that chance? Speculation was rife. Any young man can look through a microscope, perhaps he will draw the prize in the lottery of alleged science. Looking would he all right,

[1] Would it be so impossible to judge that the bacterium is an accompaniment of a chemical poison and may be present, or absent, according to the changed condition of the poison? Such changes take place all the time in putrefying material as Salkowski has shown, and others after him. They probably take place in the living body also, during infectious fevers. In the incubation they develop, they are most poisonous and vehement during the height of the process, they gradually change into less dangerous combinations, into an indifferent state, and finally a really disinfectant material. Thus it may be that the floating poison may become even beneficial. Is it for that reason that patients who have outlived a serious attack of typhoid fever, are endowed with better nutrition and more vigor afterward than they ever enjoyed before?

if he would not write. Medical life would be easier if there were less journal articles containing the latest infallible discoveries. Thus it has come to pass that German medicine has a two-fold aspect nowadays. The days of her superiority are not over yet, her greatest men still live, and the toiling thinkers are at work, but the number of speculators is immense. A great many of the articles printed in the journals of the last ten years have been prematurely published, the number of preliminary notices announcing discoveries under way is very large. The great embryo cannot wait. He is afraid of having his celebrity snatched away from him by the next door microscopist.

Thus it is that we often find a difficulty in keeping our eye on the great lights, whose rays are always welcome. If learned and thoughtful specialism has its justification anywhere, its field is the solution of the mooted questions alluded to. Thus far I claim, however, that in regard to bacteriology, the main questions are before the medical world still. I firmly hope the Academy will prove the centre of critical researches by which the problem, whether bacteric or chemical poison, still a mystery, will be carried nearer its solution.

In this expectation I am justified by a reference to the historical fragments you permitted me to sketch to-night. There has been no deviation from the empirical and clinical tendency of Anglo-Saxon medicine from the beginning. It was so strong that it gave character to the medicine of the eighteenth century. In the words of the Testament I might say, Sydenham begot Boerhaave, Boerhaave begot van Swieten, van Swieten begot John Peter Frank. Sydenham and his generation of followers are the flower of the whole century and their spirit penetrates everywhere. In those times the senses alone were the diagnostic apparatus. The exact methods of the following decades have sharpened the senses of the English and American medical men, and rendered their observations more accurate and their results more correct. Live and learn, has been their pass-word. No new methods have ever been neglected, only unfounded theories ought not to find root in the regular medical profession. As the best features of all experience and wisdom of all ages and all nations have been utilized in the establishment of our political system, thus the American medical mind has received, appropriated, and critically digested the results of foreign scientific labor and added of its own. It is with sincere pleasure that I have again read that interesting collective volume containing a century of American medical history. In it those of you who have not read it will find many a good reason to be proud of the achievements of our country. It is so modest in its tone and contents that many more names might have appeared in the enumeration of men and labors, not to speak of those who have added materially to our wealth of intellectual productions since. Its perusal will be a revelation to many who are in the habit of looking for everything new and trustworthy, and—that is the technical term now-a-days—epoch-making, from abroad. If there is anything which teaches us both justifiable pride and desirable modesty, it is the history of our science in our whole country. For besides a great many of the former and present members of this Academy who have accomplished lasting results, there are a great many other Americans in other states and cities who stand on a level with the best of all nations.

From the reading of old journals I learned but lately that four years before Semmelweiss proclaimed the contagious character of puerperal fever, against the protest of the official standard-bearers of obstetrics in Austria and Germany, our own anatomist, our philosopher, our poet, our autocrat, our own Oliver Wendell Holmes, taught, it is true, against the ridiculing sneers of Hodge and Meigs, the frequent transmission of puerperal fever by physicians and nurses. I might go on a long time, but I do not stand here to extol America or American medicine. Still I feel strongly that we may be well satisfied with what we, not protected by governmental interference, unaided by a slow growth through centuries, have accomplished in a proportionally short time. The last few decennia gave us the library of the Surgeon-General's office, the "Subject Catalogue," "The Medical and Surgical History of the War," standard books, recognized as such in Europe, great journals, and a goodly array of valuable monographs, and vastly improved college education; they have raised great surgeons and clinicians of universal reputation, and a progressive profession whose aim and best efforts are directed toward the improvement of medical training, and the sanitary condition of the people.

All this I firmly believe is true. If it were not, let us make it so. If it be, let us still rise and work, and with all that, let every man among us feel what Holmes said forty years ago: "I am too much in earnest for either humility or vanity."

PNEUMONIA IN YOUNG CHILDREN.

By L. EMMETT HOLT, A.M., M.D.,

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE NORTHWESTERN DISPENSARY, INSTRUCTOR IN THE NEW YORK POLYCLINIC.

A COMPLETE description of a disease like pneumonia, even if we limit it to early life, is not possible within the limits of a paper like this. I shall confine myself mainly to the clinical features of the disease, as deduced from a comparative study of eighty-six cases, which I have had under personal observation and whose histories have been carefully recorded.

As these cases are taken indiscriminately from private and dispensary practice they can be assumed fairly to represent the disease as it is seen outside of large institutions for children. As my object is not to establish the value of any particular line of treatment, the cases have been taken consecutively, and include all those I have seen during the period covered, at whatever stage and for howsoever long a time under observation.

I much prefer and shall use the terms lobar and broncho-pneumonia, instead of croupous and catarrhal, or lobular, to designate the two varieties. The latter terms though fairly descriptive are rather misleading than otherwise.

While broncho-pneumonia is the form essentially peculiar to early life, the lobar variety occurs often enough to demand a portion of our consideration.

Some idea of their relative frequency may be gained from the fact that of seventy-four cases under five years, eighteen were lobar and fifty-six cases of broncho-pneumonia, or about one to three. Baginsky, from a much larger number of cases, finds the same proportion. It is a mistake, then, to say that lobar pneumonia is rare under five years.

As it occurs in young children it presents the same general features as in the adult. We note its prevalence during the months of March, April, and May, its sudden invasion, its typical course, and its rapid defervescence on the sixth to the tenth day. Yet there are certain peculiarities, owing to the absence of some of the diagnostic symptoms present in adults, and the existence of certain new ones dependent on the conditions of childhood, which render the diagnosis difficult, and may cause it to be overlooked altogether without a careful physical examination. The following may be taken as an illustration of a simple uncomplicated case of average severity.

A well-nourished female child, aged ten months, after an exposure in the afternoon was taken in the evening of March 15th with vomiting, high fever, great restlessness, and cough. She was seen March 17th, with temperature, 103½°; respiration, 68; pulse, 170. Face was flushed; there was a good deal of general prostration. A patch of consolidation was found at the inferior angle of the left

scapula. Signs: Marked dulness, bronchial breathing, no râles; signs elsewhere normal in both lungs. The next day the signs of consolidation had extended over the whole left lung except the extreme apex. The fever continued high until the 19th, when a marked decline took place, and after the 20th (sixth day) the temperature was normal. In a week's time almost complete resolution had taken place.

The disease is usually primary, and occurs more frequently in stout, robust children; males a little more often than females. A distinct prodromal stage is rarely present. The disease begins suddenly; it is ushered in most frequently with repeated attacks of vomiting. This was the mode of onset in about half my cases. Next to this, convulsions seem to be the most common. A distinct chill in a young child I do not remember to have seen in a commencing pneumonia. After six or seven years it is more frequent. High fever sets in almost at once. The temperature rises to 104°, or even higher, the respiration to 50, 60, or 80 a minute, and the pulse to 120 or 160. There is great thirst. If still at the breast, the child desires to nurse almost incessantly. It seizes the nipple eagerly, pulls violently a few times, drops it for a moment, takes a few deep, quick respirations, and then catches it again. When not nursing the respiration is peculiar. There is a short, quick inspiration, a moment of suspension, and a forcible expiration with a slight moan or grunt. The expiration is accentuated, and is an active, rather than a passive, movement, as it seems to be in health. The cry, like the breathing, is short, quick, and interrupted. The cough partakes somewhat of the same character; it is teasing, hacking, persistent, and always dry. There is great restlessness and irritability, and occasionally the child complains of distinct thoracic pains. There is marked general prostration, the cheeks are occasionally flushed, but more often not, and the face is then pale and the expression apathetic. The temperature fluctuates slightly during the day, being 102° to 103° in the morning, and 104° to 105° in the evening, until the sixth or seventh day, sometimes not until the tenth, when it suddenly falls to or near the normal, and convalescence is rapidly declared. The crisis often comes with a copious diaphoresis. Although very ill as these children appear, and in fact really are, the mortality is very small. In twenty-five cases I have had but one death. The case was as follows:

A boy, aged nineteen months, rather delicate, was taken, on the evening of February 6th, with convulsions. He had lain in a drowsy, semi-stupid condition up to the time I saw him, February 8th, with a continuous high fever. There had been frequent vomiting. The temperature was 104¾°; respiration, 50; pulse, 195. Respirations were a little irregular. There was no paralysis, the abdomen was natural, the pupils normal, a few coarse râles only in the lungs, and very little cough. The next day the signs of consolidation were found in the left lower lobe posteriorly. Temperature, 104½°. On the following day—the fifth of the disease—the temperature was nearly 105° all day; once, at noon, touching 106½°. Still he seemed to be holding his own. On the sixth day the nervous symptoms became still more severe; he had screaming fits during the night, was excessively irritable, boring his head in the pillow. There was, however, no true stupor, he recognized the mother, and at times was bright. His respirations were not specially quick, 56 being the highest; there was no dyspnœa, and no cyanosis. His pulse was feeble, and rose in the evening to 200 a minute, and the temperature to 106¾°. The signs of pulmonary œdema were then present, and he died from this cause five hours later. Throughout the course of the disease the general symptoms were very severe, and apparently out of proportion to the extent of lung involved, which was only half of the left lung posteriorly. This case corresponds pretty accurately with a form described by some writers under the head of typhoid pneumonia. Unfortunately no autopsy could be obtained.

The cerebral symptoms are often so prominent as to mask completely the rational symptoms of the pneumonia. The initial convulsions may be succeeded by an active delirium, general hyperæsthesia, vomiting and constipation, or by drowsiness verging on a true stupor, with slight opisthotonus and retraction of the abdomen. The cough is often absent in such cases, and the rapid breathing may be the only symptom to call attention to the lungs. A positive diagnosis is only reached by the physical signs. These cerebral symptoms may disappear after two or three days, or may last until the crisis, when they vanish with the fall in the temperature and the beginning of resolution, as in the following case.

A delicate little girl, two years of age, was seen on the fifth day of a pneumonia complicating whooping-cough. There had been constipation, vomiting, extreme irritability, great prostration, loss of flesh, and complete anorexia. The temperature was 103⅘°, and the respiration 60. A patch of consolidation was found in the right lung anteriorly. For the three days succeeding, she presented the following symptoms: Great drowsiness, this being disturbed only by the cough, opisthotonus with rigidity of the muscles of the neck, retraction of the abdomen, the pupils responded sluggishly, the urine was scanty, the bowels constipated, the tongue dry.

This combination of typhoid and cerebral symptoms were the grounds of a grave prognosis, which was given. Yet with the occurrence of the crisis on the eighth day they all disappeared, resolution took place quite promptly, and the case made a good recovery.

Gastro-intestinal symptoms at the outset may be so severe as to engross the whole attention of the physician, and it may be several days before any pulmonary disease is suspected, as in the following case, where the pneumonia was only discovered by accident:

A stout boy, seven years of age, was taken on December 13th with severe vomiting and purging, and pain in the left hypochondriac region. I saw him at the dispensary on the 15th. He did not seem very sick, and had not been confined to bed. His tongue was heavily coated. The vomiting had ceased, but he was having from six to eight diarrhœal passages a day. Nothing was disclosed by the rather superficial examination made, and an astringent diarrhœal mixture was ordered. Two days later he was brought back by the mother, looking so sick that his case was more carefully investigated. His diarrhœa had not been in the least relieved by the prescription. He had had four passages that morning. The history of a high fever the night before, followed by a profuse sweat, led me to examine his spleen with a view to some possible malarial complication. Finding no enlargement, I casually listened to his lungs, and was greatly surprised to find all the signs of consolidation at the left apex. His temperature was 102⅘°, respiration 48, pulse 120. I ordered him to be kept in bed, and I saw him daily at the house. The diarrhœa ceased the next day, practically without treatment. The disease ran thereafter a typical but somewhat severe course, the temperature being continuously high until the night of the eighth day, when it fell to normal with a profuse sweat. Quick resolution took place.

Regarding the *seat of the disease*, lobar pneumonia in children presents quite a marked contrast with what is found in adults. My own cases are too few to give any statistics of value upon the relative frequency with which the different parts of the lung are involved. They accord, however, with those given by Rilliet and Barthez and Baginsky, that the order of frequency is, first, the right apex; second, the left apex; third, the left base; fourth, the right base. Of 408 cases from the first authors, 170 were at the right apex. Of 50 cases from the last author, in 26 the right apex was involved, though not exclusively in all.

Physical signs.—Generally speaking, these do not

differ essentially from those in the adult. The fremitus of the cry is usually increased; dulness is as a rule quite marked, though if the consolidated area be small, we may get exaggerated resonance over the whole chest. The subcrepitant râle, is, I think, more frequent than the crepitant; in fact, the latter I have rarely heard. The resonance of the cry is prolonged and intensified, the breathing is broncho-vesicular, and then bronchial. Usually pleuritic friction-sounds are heard.

The frequency with which the apex is involved should be borne in mind, and the region high in the axilla carefully examined, as it is here perhaps that the disease is most often overlooked. It is not infrequently the first, and may be only place, in which bronchial breathing is heard.

This frequency is also, perhaps, an explanation why pneumonia with cerebral or typhoid symptoms, and also central pneumonia, are comparatively so frequent in early life.

Before leaving the subject of physical examination, I wish to say a word about the use of the stethoscope. It is extremely difficult, well-nigh impossible in an infant, to examine the supra- and infra-clavicular and the high axillary regions satisfactorily and thoroughly with the naked ear. And these are just the parts we wish to be particular about. It can be done with great ease by the stethoscope. Children are less likely to be frightened into crying by the instrument, than by the head of the physician. In children of two or three years old this objection may not have the same force.

Diagnosis.—Although in most cases this is easy, it presents in some very great difficulty during the first two or three days before positive signs of consolidation appear. In central pneumonia this difficulty is greatly enhanced. In one case, in a boy of two years of age, there were absolutely no physical signs until the seventh day. Yet the rational symptoms, particularly the continuous high temperature, it being 105° and over, left very little doubt in regard to the diagnosis. The chest was carefully examined every day. The consolidation finally appeared at the extreme right apex.

Practically I have found lobar pneumonia difficult to distinguish from scarlet fever, typhoid, meningitis, tonsillitis, malarial fever, pulmonary congestion, and broncho-pneumonia.

The invasion of pneumonia and scarlet fever are very similar. We must wait for the physical signs of the one or the rash of the other before pronouncing a positive opinion. With reference to typhoid, it must be borne in mind that its course is less regular in children, and that a high temperature is more common at the outset than in adults. Considering the frequency of diarrhœa and typhoid symptoms in pneumonia, it will be seen that the physical signs and the course of the disease are the only positive means of differentiation. A source of error in the physical signs will be mentioned in another connection.

The cerebral symptoms of pneumonia are rarely so intense, so prolonged, so continuous, or so progressive as those of meningitis, although almost every individual symptom of the one may be present in the other.

I have several times mistaken the invasion of a simple tonsillitis for a commencing pneumonia. This error is likely only in those cases where the severe general symptoms are out of all proportion to the local throat changes, and precede them by a day or two. It is often hard to convince one's self that the patient has nothing more grave than a simple sore throat. This is especially common when the disease prevails as a sort of epidemic, as it does every now and then.

I have mentioned pulmonary congestion as one of the conditions with which pneumonia may be confounded. The following case may serve to make my meaning clear.

I saw, in October last, a girl, seven years of age, with a temperature of 104⅘°, respiration 55, pulse 150. She had been sick a week; mode of invasion not accurately determined. There had been headache, cough, and continuous fever, but no special diarrhœa, no epistaxis. She had been in bed most of the time. There was no characteristic eruption. Examination of the lungs gave evidence only of slight bronchitis. Typhoid was diagnosticated, though with some hesitation. The next day the lungs were again examined, and high in the left axilla bronchial breathing and bronchophony were present, and so distinct as to be undoubted. There was no special dulness. I said to a medical friend, "My case of typhoid fever has turned out to be an apex pneumonia." On the following day, greatly to my surprise, the signs at the left apex had entirely disappeared. Further examination revealed the fact of distinct bronchial breathing and voice, and slight dulness over an area half the size of my hand at the right base behind. These signs were not present the day before. I said to my friend, "I was deceived regarding the diagnosis in that case, it is pneumonia, not, however, in the left apex, but at the right base. The signs to-day are unmistakable."

At an examination made the next day I was again compelled to retract, as the signs at the right base had vanished completely. I returned to my original diagnosis of typhoid, which the subsequent course of the disease proved unquestionably to be the correct one. No further signs of lung consolidation appeared.

I could multiply illustrations of this point. These congestions, sometimes affecting a whole lung, sometimes the base, sometimes the apex, I have seen under many circumstances, most often with malarial fever. Occuring in the course of pneumonia they lead to the belief in a sudden extension of the disease. In one case the signs of consolidation had been limited to the left upper lobe in front and the extreme apex behind. On the day before the crisis they were present over the whole left lung posteriorly. The general symptoms were so much worse I thought there could be no doubt of an extension of the disease. However, as the temperature fell the next day they all disappeared, leaving the signs exactly as they had been two days before.

This subject is one of exceeding interest to me; I wish I could dwell upon it more at length. I hope in the discussion which follows some one may throw additional light upon these obscure cases. I think it is impossible by any physical signs to differentiate between congestion and lung consolidation. Congestion is only recognized by its inconstancy, its mobility, and its evanescent character, rarely lasting more than a couple of days.

The onset of malarial fever and pneumonia are very similar; both usually begin abruptly with vomiting, convulsions, or a chill; in both we have the sudden rise of temperature to from 103° to 105°. When pulmonary congestion is associated with malaria we get the same accelerated breathing as in pneumonia; and it may be even more rapid than in the latter disease. I have in several cases seen it one hundred a minute. In this condition all the physical signs of commencing pneumonia may also be present. A differential diagnosis in these cases is absolutely impossible at the first examination. Observation of the patient for a day or two, especially noting the temperature curve, usually clears up the case beyond all doubt. In malaria there is almost invariably a marked morning remission. If the lungs are examined then, the physical signs will be found in many cases to have vanished completely, or at least to be insignificant. There is one symptom which has in several cases saved me from unreserved diagnosis of pneumonia in these malarial cases. This is the amount of general prostration; it is almost never so marked as in pneumonia.

The differential diagnosis from broncho-pneumonia will be considered under the latter disease.

BRONCHO-PNEUMONIA.

By this term I understand an inflammation which affects the mucous membrane and the walls of the bron-

chi, the air-cells, and the interstitial tissue of the lung. The bronchial element predominates, in fact forms the characteristic feature.

Dr. Francis Delafield mentions ("Pathological Studies," 1883) certain anatomical peculiarities of the child's lung which in part account for this. He says, "the bronchi occupy relatively a larger portion of the whole organ; the interstitial tissue is present in larger amount; the cavities of the air-cells are smaller and their walls thicker."

All the latest writers upon the pathology of this disease agree that we can no longer draw the line between broncho-pneumonia and that condition formerly described as capillary bronchitis. The terms are used synonymously. This form is spoken of as generalized, diffuse, or disseminated pneumonia.

Without going fully into a description of the lesions of this disease they may be summarized briefly as follows: 1, Inflammation of the mucous membrane of the bronchi of all sizes; 2, infiltration of their walls with inflammatory products; 3, acute dilatation of the small bronchi from these changes; 4, zones of hepatization and congestion surrounding the bronchi; 5, collapse of groups of air-cells from bronchial obstruction; 6, extensive congestion of areas neither collapsed nor hepatized; 7, more or less diffused areas of hepatization; 8, exudation of fibrine on the pleura; 9, infiltration of the bronchial glands.

In addition, it is necessary to remember certain conditions affecting the organs of respiration and circulation in children, which do not obtain in adults. The right ventricle of the heart is at birth as thick as the left. Throughout childhood it is relatively much more powerful than in adult life. Hence, it is better able to perform the increased work thrown upon it, by the obstruction to the pulmonary circulation in pneumonia. In this respect the child has a decided advantage over the adult.

Precisely the opposite is true with reference to the respiration. A healthy child produces, according to its body weight, about twice as much carbonic acid as an adult. The pneumonia renders a certain portion of the lungs practically useless for the time, while the febrile process increases the production of carbonic acid, far beyond the quantity in health. Hence, although the child needs more breathing space it actually has much less. Again, the respiratory muscles are not so well developed in early life, and these are weakened by the disease itself. Furthermore, a great amount of the muscular force exerted is lost, because of the yielding chest-walls and the great bronchial obstruction. The latter is due, not only to swelling and the accumulation of secretions, but also to spasm, which plays no unimportant part in a large number of cases. With each inspiration the bronchial secretions are drawn further and further toward the alveoli. The expiratory force being stronger than the inspiratory, more and more air is forced from the air-cells, until they collapse in great numbers, and the chest muscles become exhausted by vainly trying to lift its walls against the atmospheric pressure.

From the facts I fully agree with the conclusion reached by Baginsky, "Pneumonia und Pleuritis," p. 42, that while adults die in pneumonia mainly from heart failure, in children it is the failure of the respiration. This point has, I think, an important practical bearing.

The sexes in broncho-pneumonia are about equally affected, possibly there is a slight predominance of females.

Of fifty-three cases it was presumably primary in seventeen, or about one-third. In ten it complicated whooping-cough; in nine, measles; in nine it followed a primary bronchitis; in the remainder it was secondary to cholera infantum, scarlatina, vaccinia, or malaria, dentition co-existing in several instances.

Only some of the cases were over three years of age. Both lungs were almost invariably involved, although generally to a different degree. The disease is always more intense behind than in front.

The clinical picture presented by broncho-pneumonia is a decided contrast to the lobar form in most of the prominent features. It is nearly always secondary; attacks children debilitated by previous disease; its onset is gradual; it rarely terminates by a crisis, and has no typical course. When it supervenes upon an attack of bronchitis it may be so gradually that it is difficult to tell exactly when the extension took place.

The temperature curve is an exceedingly variable one. It is not so uniformly high as in lobar pneumonia. The diurnal variations are usually greater. The most common course is for it to run from 101° or 102° in the morning to 103° or 104½° in the evening for about ten days, when it subsides gradually, being a week or ten days more before it finally remains normal. Very often the duration of the febrile stage is four weeks instead of three.

In one-fourth of my cases it reached 105° or over. In three it was 106⅝°; one of these cases recovered.

While in general it is true that the disease is dangerous in proportion to the height of the temperature, yet I have seen death occur as early as the tenth day where the temperature was only once above 101°.

The respirations are always much accelerated. They are more rapid and more labored than in lobar pneumonia. They usually range from sixty to eighty per minute. In severe cases their number rises to ninety, one hundred, or even one hundred and twenty, as I saw in one case.

Let any one try to breathe even eighty times a minute for a few minutes, and he will understand why these children become exhausted.

The pulse generally rises with the temperature and the respirations; it reaches one hundred and fifty to one hundred and eighty. I have several times seen it two hundred and over.

The amount of general prostration is not so great at first, perhaps, as in lobar pneumonia; but as the disease progresses it becomes extreme. The children lie preferably upon the back, often too weak or too apathetic to make any resistance to examination. The cough is nearly always distressing. But I know of few things more painful to witness than a child exhausted with pneumonia struggling with a paroxysm of whooping-cough when this complication exists. It seems as though every seizure would be the last.

Toward the close of the disease the drowsiness is much increased, probably from carbonic-acid poisoning; true coma rarely is present. Other patients continue in a state of extreme nervous irritability, tossing from side to side in great distress, making violent but ineffectual efforts to get more air into the lungs. Sometimes convulsions develop; these usually end the scene.

The face is quite characteristic; it is pale and indicative of suffering and anxiety. The alæ nasi dilate with each inspiration. Later the lips become livid, and the face slightly cyanotic.

The cry is short, and usually feeble and whining.

The disappearance of the cough is always a bad symptom, and is an indication of general blunting of sensibility from the blood-poisoning.

Death usually occurs during the acute stage from asphyxia and exhaustion, the heart failing after the respiration.

Physical signs.—In all cases of thoracic disease in infants and young children we encounter difficulties not met with in the adult. These are partly incidental, depending on the irritability of the child and its resistance to the examination, and partly inherent, from the fact that the child cannot give us assistance by regulating at will the frequency and the depth of the respiration, and also that the voice sounds are but imperfectly replaced by the cry. The very rapidity of the respiration itself becomes a source of embarrassment.

Palpation.—The information afforded by this sign is not of great value. The thin chest-walls allow the transmission of all vibrations with distinctness, whether they are nasal, laryngeal, tracheal, or bronchial in their origin. When this fremitus is felt all over the chest it sig-

nifies little; when exaggerated in areas distinctly circumscribed, it has the same value as in the adult.

Percussion.—Can only give positive information when the lobules hepatized are numerous and close together. When a large part of a lobe is involved, we get dulness which may be as marked as in lobar pneumonia. When the patches are smaller and scattered, which is more frequently the case, the dulness is slight. In those cases where the pneumonia is generalized, involving a large part of both lungs to the same degree, the whole chest may be extra-resonant. The emphysema which always exists about the patches of consolidation, modifies the percussion note behind, and produces the exaggerated resonance almost invariably present in front and over the apices. It is upon *auscultation*, then, that we must mainly rely in the diagnosis of this disease.

The sibilant râle is usually the first sign in the generalized or "suffocative" cases. It then develops very rapidly and may be heard over nearly the whole of both lungs. Vesicular breathing may be almost absent from the obstruction in the bronchi. These râles, when thus generalized, are replaced in a day or two by mucous clicks and moist râles of all sizes equally diffused. These may be the only signs during life.

The respiratory murmur in some cases is simply very much exaggerated or ultra-puerile, so that the breathing usually heard in front and at the apex is heard all over the chest. This is especially in cases where the breathing is very rapid. It may vary from this, through all the degrees, vesiculo-bronchial and broncho-vesicular, to pure bronchial breathing. Absence of vesicular breathing does not always mean hepatization. It may be due to great obstruction in the bronchi with collapse of the air-cells, or to congestion. Pure bronchial breathing, such as is heard in lobar pneumonia, does not usually exist. When it does it is combined with the other signs, marked dulness and increased resonance of the cry, which are found in that disease.

Usually we have a commingling of pulmonary and bronchial sounds, and either element may predominate. The breathing, in most cases, is only broncho-vesicular, high-pitched, particularly the expiration, which is prolonged. Sometimes the râles may completely obscure the breathing sounds. The pitch of the râles thus gives valuable information. When consolidation exists this is high, and they have a sharp, metallic character. The exaggerated resonance of the cry is also valuable here. Auscultation during, or immediately after a paroxysm of coughing, may serve to disclose signs of consolidation not otherwise perceived. As râles over the upper lobes are generally less abundant, changes in respiration here are more easily made out.

Where the pneumonia supervenes upon a bronchitis it is impossible to tell precisely by the physical signs when this extension occurs. Signs of consolidation rarely appear before the third day, and often not until the seventh or eighth.

When a consolidated area exists in one lung the transmission of the sounds to the opposite side may be so distinct as to lead to the supposition of disease there. Percussion usually enables us to correct this mistake. A more common source of error is that, when the breathing is very rapid, and consequently very superficial, laryngeal and tracheal sounds, and those produced in the primary bronchi, are transmitted and audible over the whole chest, but are particularly loud in the interscapular regions. Here they closely resemble bronchial breathing from consolidation. The fact that the same thing is heard upon both sides, and that there is no dulness, usually suffices to distinguish it from the latter condition. In all cases the signs vary greatly from day to day, changing with the depth of the respiration, the position of the child, etc. Repeated examinations are always necessary before pronouncing positively in regard to the condition of the lungs.

(To be continued.)

ON THE LOCALIZATION OF THE CORTICAL MOTOR CENTRE OF THE LARYNX.[1]

By D. BRYSON DELAVAN, M.D.,

[NEW YORK.

In the light of important discoveries made in recent years by such investigators as Ferrier, Charcot, Hitzig, and others, the theory that there reside in the cortex of the brain definite centres of muscular action, has slowly but steadily gained a strong position in physiological science, and has attracted the support of a large and constantly increasing number of competent observers.[2]

Although, as the outgrowth of these studies, much has been done to determine the motor centres of other organs, general and special, the centre for the human larynx has, up to the present time, remained an unexplored field.

It will be the object of this paper, therefore, to call attention to certain anatomical, physiological, and pathological considerations, which, if they do not actually prove, at least strongly suggest, the probability that such a centre does exist, and, secondly, to indicate, as nearly as may be, the precise location of this area.

I. In regard to the anatomical considerations, it has long ago been shown that the cortical centre for the lower limbs is in the region of the superior part of the fourth frontal and the ascending parietal convolutions; that for the arms in the middle part of the ascending frontal; that for the face in the inferior part of the ascending frontal; while that for speech occupies the lower part of the third left frontal, toward where it joins the ascending frontal.

By analogy, it would be natural to expect to find the centre for the larynx in the vicinity of the centre for the movements of the face and for speech.

As to its nutrition, this whole motor region, adjacent to the fissure of Rolando, is supplied by one of the branches of the middle cerebral artery. According to Quain,[3] the main trunk of the middle cerebral artery passes upward and outward to the fissure of Silvius, until it reaches the Island of Reil, on the surface of which it divides into four branches. The first branch is limited in its distribution to the outer part of the orbital surface, and the adjacent inferior frontal convolution. The second branch supplies the posterior part of the middle frontal, and the chief part of the ascending frontal convolutions. The third branch passes in the fissure of Rolando to the rest of the ascending frontal and to the ascending parietal convolutions, and to the anterior part of the superior parietal lobule; and the fourth, lying in the posterior branch of the fissure of Silvius, supplies the inferior parietal lobule and the superior temporo-sphenoidal convolutions. Again, the cerebral arteries anastomose but sparingly at their extremities, so that each branch supplies, as it were, a territory of its own.[4] "All of the nutritive arteries are end arteries,"[5] while some of the smaller branches distributed to the cortex are also of this nature.

II. *Physiologically.*—At a meeting of the Physiological Society held in Berlin, November 23, 1883,[6] Dr. Herman Krause stated that he had, in the laboratory of Professor Munk, investigated experimentally the supposition that the voluntary muscles of the larynx would be found to have a cortical centre, and had confirmed it. On exposing a dog's larynx, and irritating a certain section of the cortex by moderate electrical currents, he invariably noticed the rise of the larynx, the movement of the vocal bands to a position midway between expiration and phonation, the rising of the palate, the contraction

[2] Of the practical value of a complete knowledge of the functions of the brain-cortex in the diagnosis of pathological conditions of that organ, both medical and surgical, it is not necessary here to speak. For a most graphic and interesting exposition of the subject in general in its relation to surgical diagnosis, the reader is referred to the excellent work of Dr. J. Lucas-Championnière, Paris, 1878, entitled La Trépanation Guidée par les Localisations Cérébrales.

of the constrictor pharyngis, and movements at the base of the tongue.

That the part of the cortex in question was the centre of the laryngeal movement was further confirmed by experiments of extirpation, which were performed successfully on both sides in ten dogs.

The cortex was experimented on, first on one side and then on the other, and after all the inflammatory symptoms had subsided, and the cerebral wounds were cicatrized, or in process of cicatrization, it was found that eight dogs had entirely lost the power of barking, and, on attempting to bark, uttered either no sound or only a hoarse whine. In the case of the two dogs which, after the operation, continued able to bark, it was shown that the excision had not been properly performed.

From these experiments it would appear that there is, in the brain of the dog, a cortical centre for the muscles of the larynx.

III. With the foregoing data at our command, the significance of the pathological evidence offered by the following very rare cases is particularly striking.

Case I.—Male, aged sixty; retired merchant; family history excellent, except for rheumatic diathesis. Has always been very strong and healthy, of regular habits, and strictly temperate in the use of alcoholics, but an immoderate tobacco smoker. Since middle life has suffered much from rheumatism, and has rapidly accumulated fat, but gives no history of any other diathesis. Has also suffered from naso-pharyngeal catarrh. Is right-handed.[1] In 1876 had a slight attack, attended with vertigo, partial insensibility, and numbness, but without any distinct paralysis. A year later was again attacked, this time with well-marked hemiplegia. Although complete insensibility was at no time present during the attack, there was intense pain in the back of the head and in the nose on the left side, numbness and impairment of motion of the left arm, side, and leg, almost total inability to swallow, and, finally, a remarkable change in the quality of the voice, which, from having been full, deep, and sonorous, was reduced to a cracked, piping, and uncertain tone, which rendered its use almost impossible. Articulation was also impaired, the patient for months afterward being obliged to pronounce each syllable separately, speaking slowly and with difficulty. There was at no time or to any degree aphasia.

There was distinct ptosis, with paralysis of the left side of the face and tongue. After continuing two or three days the general symptoms began to subside, beginning with the leg, then the arm, and last of all the face, and slow but steady improvement continued for many months in all the above-mentioned conditions except the voice. In this there was little apparent change for some time, but by degrees it became more readily controlled and less discordant, although the high-pitched quality has continued up to the present time, together with the loss of power and inability to force it. In 1882 a laryngoscopical examination showed the existence of a complete paralysis of the left vocal band, the position of which was, apparently, in the median line. The larynx was remarkably easy of demonstration, and the diagnosis was afterward confirmed by Dr. Clinton Wagner. Laryngoscopic examinations made at intervals since 1882, the last one on June 12, 1884, have demonstrated no change in the position of the cord. Efforts made to determine the electrical "reaction of degeneration" have not, thus far, proved successful. To summarize, in a case of common left hemiplegia, in which pharyngeal and laryngeal paralysis were especially well marked, all of the symptoms have disappeared in regular order except those relating to one set of muscles, namely, the laryngeal abductors of the left side; and these have continued paralyzed for a period of seven years.[1]

Case II.—Seguin[2] reports a case in which, with common hemiplegia of the left side without loss of consciousness, speech was much impaired by defect in articulation. The paralysis passed away rapidly, but the power of articulation was never wholly regained, the patient never afterwards being able to control the pitch of the voice, apparently from a lack of proper action of the muscles of the pharynx or larynx. No laryngoscopic examination was made. Later, the patient died from another hemiplegia, this time of the right side and complete, with absolute aphasia.

Autopsy.—Membranes and sinuses of brain normal. Surface of third frontal convolution of the right side yellow in color, with a tough elastic feel. This lesion, extending through the gray matter, was about an inch square and a quarter of an inch thick. The same change, but to a less extent, was found in the same location on the left side. The left middle cerebral artery was plugged by an embolus at a point one-half an inch from its origin. A spot of brain about one-half an inch in diameter, supplied by this artery, was in a softened state.

"An interesting feature of the case," says Dr. Seguin, "is in connection with the very localized lesion in the right hemisphere and the first attack of hemiplegia, characterized by slight and transitory paralysis of the limbs, and by very great defect in articulation. Indeed, the patient never recovered the full use of her vocal organs. From this we may infer that the function of the third frontal convolution, on the right side in right-handed human beings, is intimately connected with the muscles governing the movements of articulation and phonation."

The diagnosis made in Case I. was, endarteritis of the third branch of the middle cerebral artery. From the reference before made to the anatomy of the brain it is evident that the motor-centres supplied by this artery were affected, namely, the centres for the leg, the arm, and the face. That the larynx was also paralyzed indicates that the motor-centre for the larynx was in the course of the occluded vessel. The blood-supply of the region, gradually restored by anastomosing branches, first returned at the terminal extremities of the anterior branch. Hence the leg was first to regain its normal function, afterward the arm, and later still the face. That the laryngeal centre was permanently paralyzed may be explained on the supposition that the arterial branch supplying it was an "end-artery," given off remotely from the distal or terminal extremity of the main trunk, so that anastomosis was not present, and its circulation could not be re-established. That the same accident may have happened in Case II. is conjectured by the position of the lesion found *post-mortem* upon the right side of the brain, as well as by the marked similarity of the resulting symptoms. In reviewing the above several points are worthy of especial mention:

a. The lesion was in both cases upon the right side of the brain. Irritation of the corresponding part upon the left side, in right-handed persons, produces aphasia.

b. In both cases the same muscular groups were affected, and in apparently the same manner.

c. In both the general symptoms in the same manner disappeared.

d. In both paralysis of the larynx was permanent.

Of course, while it must be admitted that upon a basis so slender as that afforded by these two cases, unique in the history of the subject, it is impossible to build any certain and unimpeachable deductions. Still, in the light of our present knowledge, and from the study of the considerations herein adduced, anatomical, physiological, and pathological, the following conclusions seem justifiable:

1. That there is a cortical centre of motion for the human larynx.

2. That this centre is in the course of the third branch of the middle cerebral artery.

3. That it is toward the proximal end of this vessel.

4. That it is in the vicinity of the convolution of Broca.[1]

[1] Case I. has already been reported in the New York Medical Journal.

JEQUIRITY AS A REMEDY FOR GRANULAR LIDS WITH PANNUS.[1]

By DAVID WEBSTER, M.D.,

NEW YORK.

My object in this brief paper will be to call your attention, as general practitioners, to a remedy the use of which has hitherto been confined, almost exclusively, to the specialist. Probably every physician residing at a distance from the larger cities has encountered, at one time or another, one or more cases of obstinate and inveterate granular lids with pannus, which have wearied his patience and baffled his every attempt to cure them. When possible, the general practitioner refers these cases to the specialist, and is glad to be able thus to shift the responsibility for their care. But not infrequently circumstances render such a disposition of the patient out of the question, and the physician has to struggle along with the case as best he may. After many months of treatment with sulphate of copper, nitrate of silver, and the various astringents, the eyes meanwhile getting no better, but if anything, worse, the doctor gets tired of seeing the patient whom he feels that he is not benefiting, and the patient gets tired of going to see the doctor, from whom he feels that he is receiving no benefit; so scientific treatment is abandoned and perhaps the eyes are lost, or the patient becomes the ready prey of the peripatetic vender of eye salves, eye-waters, and other nostrums.

It is to such cases as these that jequirity is applicable, and in many such cases its curative effects will be found to be little short of the marvellous.

The remedy is not entirely free from danger, however, and should always be used intelligently and with care. Some of the most skilful ophthalmic surgeons, at home and abroad, have lost eyes from its use; but that was when not so much was known of the effects of the drug as at present, and when they were experimenting with stronger solutions, and in many different kinds of diseases of the eye.

I think if the physician will observe the following rules he will find the remedy efficacious, without being very dangerous: 1. Use the drug only in cases in which considerable pannus exists. 2. Use nothing stronger than a one-fourth of one per cent. solution. 3. Make the application only once a day, and do not repeat it after the characteristic inflammatory reaction begins to show itself.

Dr. G. W. Hale, Assistant House Surgeon of the Manhattan Eye and Ear Hospital, weighed several of the jequirity beans in my presence, and found that the average weight of each bean was almost exactly one grain and a fourth. If we use, then, one jequirity bean to the ounce of water in making our infusion, we get a solution of very nearly one-fourth of one per cent. in strength. As the preparation is apt to become worthless after it has stood for more than a week, it has been my practice to have it made up fresh for each patient, and for this one jequirity bean, finely powdered and put in an ounce of cold water, is sufficient. After standing from four to six hours the solution should be filtered and is fit for use.

The infusion should be applied very thoroughly. I usually paint some of it upon the everted eyelids by means of a little cotton twisted about the end of a small stick, and then let the patient bathe the lids with the rest of the infusion for five or ten minutes. This process should be repeated once a day until the jequiritic inflammation is produced. Generally only one application is needed. The next day the patient will show more or less general febrile disturbance, the eyes will be irritable and watery, the lids more or less swollen, and the conjunctiva covered with a thin whitish membrane.

As before stated, this condition being brought about, I do not repeat the application. If the symptoms are not severe, I do nothing but have the eyes bathed from time to time with hot water. If there is considerable pain and a good deal of swelling of the lids, I apply iced cloths and atropine. The inflammation subsides in a few days, and with its subsidence the granulations and the pannus rapidly disappear. If after a month or two the improvement seems to have ceased, and the cure is imperfect, some vascularity of the cornea still remaining, the application may be repeated with further benefit.

The remedy has been used in many cases in the Manhattan Eye and Ear Hospital, by my colleagues as well as myself, and I have yet to learn of any case in which we regretted having used it. Of course it does not cure in all cases.

Clinical Department.

COCAINE IN GENERAL PRACTICE.

THE more cocaine hydrochlorate is tried in general practice, the wider is found to be its range of applicability, until now it bids fair to step into the front rank of therapeutical agents, elbowing opium, quinine, and the other few indispensable drugs. It is, of course, of exceeding value to the ophthalmologist, but it promises to be of even greater value, because benefiting the greatest number in the hands of the general practitioner. The following reports are corroborative of this prediction.

In dental practice.—Dr. B. W. Jones, of Vulcan, Mich., writes that he was called to see a lady suffering from pain and hemorrhage consequent upon the extraction of a tooth. The tooth had been removed three days previously, and had been broken in such a way as to require considerable cutting away of the alveolar process to permit of its extraction. When first seen, the patient was suffering intense pain and was very weak from loss of blood. She stated that the pain and hemorrhage had continued without remission for twelve hours. The wound was inflamed and angry looking. A pledget of cotton soaked in persulphate of iron solution was pushed into the wound with the effect simply of increasing the pain. The application was repeated a second time without lessening the hemorrhage. The wound was then cleansed of all clots, and some cotton wet with a four per cent. solution of cocaine inserted into the opening. In less than three minutes the pain ceased entirely, and at the end of ten minutes, when the cotton was removed, it was found that the bleeding was also arrested. The wound looked clean, there were no clots, and there was no sen sation on slight pressure. A second application was now made, and the patient experienced no further inconvenience.

In venereal practice.—Dr. W. C. Wile, of Sandy Hook Conn., sends the following note: "I have had two cases recently of chordee, accompanying gonorrhœa, in which the trouble yielded readily to the soothing influence of an injection of the hydrochlorate of cocaine. The first case was one of those obstinate cases that we sometimes meet with which seem to defy all treatment, and I had tried almost everything in my efforts to relieve. I gave this man an injection of ten drops of the four per cent. solution diluted with thirty drops of water, working the fluid along the urethral canal until all the mucous surfaces were bathed in it, and allowing it to remain in contact with them for a few minutes. From this time I had no further trouble with either my patient or his chordee. In the second case a similar result was obtained.

In neuralgia.—Dr. W. B. Brown, of Bath, N. Y., injected hypodermically five drops of a four per cent. solution for the relief of a paroxysm of neuralgia involving the area supplied by the supraorbital nerve. The patient had suffered for several weeks from violent and long-continued paroxysms, which could be controlled only by large and

frequently repeated doses of morphia. The injection was made deeply in the immediate vicinity of the superorbital foramen, with the result of cutting short the attack within fifteen minutes. Since that time the trouble has recurred but twice, and then in so mild a form as to require no treatment. Dr. Brown suggests a similar use of cocaine in sciatica, in place of injections of chloroform, which he has found of no value.

In teething of infants.—Dr. James Erwin Baker, of Lancaster, Pa., praises cocaine for its quieting effect in the peevishness of teething infants, and for its value in procuring sleep in such cases not only for the baby, but for its parents as well. He writes that he used the drug in the case of his own child, who was cutting his first teeth, and was very restless and irritable. A four per cent. solution was rubbed on the mucous membrane firmly by means of absorbent cotton. "After two applications, two minutes apart, the child ceased screaming, went to sleep within five minutes, and slept for three hours uninterruptedly." During the following day two applications were made with the result of quieting the child almost instantly, and without inducing any bad effects. A certain stiffness of the tongue was noticed after the application, due probably to the anæsthetic effect of the drug. A whitening of the mucous membrane, caused by the capillary contraction, was also observed. Dr. Baker adds that the results obtained in this case suggest the employment of cocaine in the diarrhœa due to the reflex irritation from teething, and he proposes to try it at the earliest opportunity.

As an inhalation in phthisis.—Dr. James E. Baker writes further that he has used cocaine with happy effects in phthisical cough. Five minims of the four per cent. solution, with a like amount of chloroform, were dropped upon an inhaler and thus taken at bedtime. In two cases of this kind he succeeded in giving the patients a better night and making them more comfortable than he had been able to do by any other mode of treatment.

In operation for entropion.—Dr. Walter B. Johnson, of Paterson, N. J., operated upon a man, seventy years of age, for the correction of entropion by removing a parallelogram of skin from the infra-ocular region. On October 18th he operated on the left eye; "used the two per cent. solution of Merks' hydrochlorate of cocaine, dropping in six or eight drops every five minutes for fifteen minutes, and although the patient complained of the operation hurting him, it was evident from his actions that the pain was not as severe as is usual in such cases. On October 21st, the right eye of the same patient was operated upon in the same manner, except that the cocaine was used hypodermically; three minims were injected below the inner canthus, and three minims below the outer canthus. The operation was then proceeded with, and upon its completion the patient said 'it did not hurt him anything to speak of,' and he exhibited, during the operation, no evidence of pain."

Regarding operations upon the eye itself, Dr. Johnson writes:

"Operations for removal of foreign bodies were all done without any pain whatever, when the two per cent. solution of Merks, or the two or four per cent. solution of Foucar, was used. In most cases, however, patients complained of smarting on the instillation of Foucar's solution. An operation for squint, one for iridectomy, one for symblepharon, and a cataract extraction, were all done, pain not being present, and the patient all the time controlling his or her eye and keeping it in any position directed by the operator."

As a mydriatic.—Dr. H. B. Grove, assistant surgeon to the Buffalo Eye and Ear Infirmary, sends an account of the results of upward of a hundred observations made by him of the mydriatic properties of cocaine. He used solutions of the strength of one, two, and four per cent. in his own and patients' eyes, and also in the eyes of rabbits. He made his own solutions and found that they remained clear for about two weeks, after which time a fungoid growth appeared. This weakens the anæsthetic power of the drug, but does not apparently influence its mydriatic properties. As far as dilatation of the pupil goes, a one per cent. solution acts as energetically as a four per cent. Dilatation begins in from four to twenty minutes, and, with a one per cent. solution, reaches its maximum in thirty minutes; it remains stationary for about an hour, and then gradually diminishes, but does not wholly disappear until the expiration of about fourteen hours. With a four per cent. solution the maximum is attained in thirty-five minutes, and the pupil does not return to its normal size under twenty-four hours. With four per cent. solutions there was partial paralysis of accommodation, for the near point of acute vision receded two inches. One curious fact observed by Dr. Grove was the difference in time required for the dilatation of the irides of different colors. In dark-brown eyes dilatation did not begin until the expiration of from ten to twenty minutes, usually about fourteen. But when the irides were blue never more than ten minutes were required. In ordinary cases, the writer thinks that cocaine is an efficient mydriatic for ophthalmoscopic examinations, but where extreme dilatation is needed atropine should be used. Dr. Grove notices the same fact that was reported by Dr. R. McDonald, of Chelsea, Mass., in a previous issue of THE RECORD, as occurring in his own person. He writes: "In granular lids, with and without pannus, I have used cocaine often, causing perfect anæsthesia to the application of the copper crystal. As a rule, however, severe pain came on in fifteen minutes, and continued much longer than at those times when the drug had not been employed."

Progress of Medical Science.

CHOREA CURED BY HYPNOTISM.—Dr. Beaunis reports the cure of a case of chorea through the influence of hypnotism. The patient was a girl twelve and a half years of age, and was suffering from her fifth attack of chorea. Dr. Beaunis had been informed by Prof. Bernheim of the result of hypnotism in a similar case, and decided to have it tried. The result was that as soon as the child was hypnotized all choreic movements ceased, and when asked to write, instead of meaningless scrawls, her writing was steady and legible. The séances were continued for some days, and the child was cured completely.

PRIMARY TUMORS OF THE SOFT PALATE.—At a recent meeting of the Pathological Society of London, Mr. Treves (London *Lancet*) exhibited two cases of primary tumor of the soft palate. The first patient was a man sixty-eight years of age. The tumor occupied the whole of the left side of the soft palate. It was first noticed eight months before the man came under treatment. A precisely similar growth had been removed from the same part of the palate, thirty-seven years ago, by the late Mr. Luke. Mr. Treves ligatured the left common carotid, and removed the growth, together with the whole of the left half of the palate. The tumor had been examined by Mr. Eve, and proved to be an alveolar sarcoma. The mass was faintly encapsuled, and there was no glandular implication. The patient made a rapid recovery. The second patient was a man fifty-six years of age, who presented a tumor the size of a chestnut on the right side of the soft palate. It had been first noticed two months before the man's admission into the London Hospital. Mr. Treves ligatured the right common carotid and removed the tumor as in the previous case. The patient made an excellent recovery. Mr. Eve had reported that the tumor was an adenoid carcinoma. Mr. Treves alluded to the great rarity of primary tumors of this part. He had found isolated records of all forms of connective tissue tumor in this region, of adenoid cancer, of so-called myomata, of vascular growths, of pure papillomata, and of dermoid cysts.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 14, 1885.

THE THIRTY-EIGHT STATE MEDICAL SOCIETIES AND THEIR TRANSACTIONS.

WE have before us an ominous pile of documents of which the titles are "Transactions of the State Medical Society of," etc., at the annual session in 1884. For many years now, we have watched the gradual heaping up of similar volumes, as they came in month after month, until at last the genetic activity of spring became crowned with the happy and complete parturiency of winter. We have laid them away with respect and tenderness, enjoining for them the Nirvana of a complete isolation and repose, which is the true immortality. Even the gentle flap of the dust-brush was proscribed. Now, however, we fear that these quiet days are over. The "Transactions" are increasing in number, doubling in size, enlarging in scope, improving in typography, putting on delicate tints of gray, and lavender, with stiff covers, steel plates, and gilded tops. We have felt obliged to peer into the heretofore virgin recesses between the covers, and vicariously, through our literary critic, to consult some of the articles there found.

The number of State Medical Societies is now thirty-eight, viz., two in New York, and one in every other State except, so far as we can learn, Nevada. The work which these organizations are doing is unquestionably improving in each successive year. This is shown not only in the better quality of the papers read, but in the greater unity and more agreeable social relations of the profession, as well as in the increased political and legislative influence in which such work has resulted. This progress appears most decidedly marked in some of the Western societies, the contents of whose Transactions is generally of a better quality than that of many of the Eastern and Southern associations, where one sees, unfortunately, too much evidence of old fogyism and the "machine."

Every one who has had some experience in the matter knows that it requires a great deal of skill and labor to conduct a State medical society so that its meetings shall accomplish the most possible good. Like all organizations in these days, it is liable to be captured and "run" by a few who have a certain natural capacity for "affairs." All such societies, to be sure, must be conducted mainly by a few who have an aptitude for the work, and who are willing to sacrifice some of their time in devotion to it. And these individuals deserve prominence and consideration for their services. The danger lies, however, in their finally substituting too largely their own interests and ambition for those of the society.

Another difficulty lies in satisfactorily disposing of a certain class of men who are always on hand with prolix papers and tedious talk.

Looking over the two or three hundred articles which appear in the various Transactions of last year, one is forced to conclude that but a very small proportion of them actually contribute to the progress of medical science or art. Most of the papers are, rather, gossipy accounts of personal experience, and expressions of personal opinion which may or may not have value. We would not, however, judge these contributions harshly, but are quite aware that State Medical Societies have it as one of their objects the relation of such experiences. Dr. A. wishes to learn how Dr. B. treats diphtheria, what Dr. C. gives in typhoid fever, and how often Dr. D. is performing version or using the forceps. In this way he is kept *en rapport* with his fellows, and an important object in the meetings of medical societies is accomplished.

A good deal of time and paper seems often to be wasted in presidential addresses, which ought in reality to be simply messages directing the attention of the society to the various measures which it should pursue. But the old-fashioned oration, with its fine allusions to the nobility of the medical calling, its illumined past and roseate future, is something that custom has made part of a State society's being, and any change must come slowly. Perhaps, after all, it is a good thing to have the heroic and poetical side of our too realistic calling occasionally portrayed.

The thirty-eight State Medical Societies will soon begin their work, and we shall record, as fully as need be, their proceedings. We confidently believe that when the year is out the evidence of a progressive usefulness of these organizations will be plainly shown.

THE EXPECTATION OF SICKNESS.

WE hear much of death-rates, but comparatively little has been known or written about sick-rates, which, after all, ought to interest the physician more.

Dr. Cl. T. Campbell, in the February number of the *Popular Science Monthly*, has called attention to the facts which can be gained regarding this latter subject by a study of the returns of benefit societies. This is particularly the case in England, where these societies are under government supervision, and are obliged to make regular returns. In America the case is different. Dr. Campbell has, however, succeeded in collecting a good many data regarding the Society of Odd-Fellows. This is one of the oldest and largest benefit societies in the country, it having been in operation for sixty-four years, and its membership being about half a million. This membership consists of healthy white males of twenty-one years and upwards. From a careful study of these records Dr. Campbell deduces the conclusion that the death-rate of the average adult male population is about 12.7 per 1,000. The actual mortality for the whole United States as estimated in the last census was about 18 per 1,000. Dr. Campbell finds that on the most favorable estimate the death-rate of the better class of adult males in the tropical States is twice as high as it

is in the temperate zone, being for the former 30 per 1,000, for the latter 15 per 1,000. If this is correct, it seems incredible that the census estimate of 18 per 1,000 is not too low.

Taking up, then, the subject of sick-rates, the following table is prepared, exhibiting the death-rate and the weeks' sickness per member among about four hundred and fifty thousand individuals :

Locality.	Deaths in 100.	Weeks' sickness per member.
Northern States.....	.70	.266
Central "	.90	.439
Western "	1.08	.665
Eastern "	1.11	.754
Southern "	1.42	.946

From studies of special returns, and by making proper allowances, Dr. Campbell reaches the conclusion that the average sickness of the better class of the adult male population of the United States and Canada is one week and a half each year.

Finally, a very interesting and useful table has been compiled from the returns of the Society of Odd-Fellows with regard to the expectation of sickness for each year of a person's life. Since a physician's scientific and personal interests are so closely dependent upon "expectation of sickness," we present the table in full. It will be seen that the amount of sickness to be expected increases with each year of life, so that while the young man of twenty-one is ill only half a week, the man of sixty is ill about two weeks and three-quarters every year.

Age.	Expectation of life—years and decimals.	Expectation of sickness for that year—weeks and decimals.	Age.	Expectation of life—years and decimals.	Expectation of sickness for that year—weeks and decimals.

THE INFLUENZA COCCUS.

The micro-organisms of disease continue to claim a large share of the attention of the medical profession. New bacilli and cocci are described in such rapid succession by the experimenters and scientists who devote themselves to bacteriology, that the general practitioner experiences considerable difficulty in keeping pace with the latest discoveries. The coccus of influenza is one of the most recently discovered microbes. Fortunately we are not asked by its prudent discoverer to at once accept it as the undoubted cause of the malady.

Dr. Seifert, of Würzburg, who first saw the microbes in question, merely gives an account of his observations, which were limited and do not in the least warrant any decisive or final opinion. His observations relate to a small outbreak of epidemic influenza that happened recently at Würzburg. They are published in No. 240 of the *Sammlung Klinischer Vorträge*. The author states that, in all cases examined by him, microbes were discovered in the patient's expectorations. He has bestowed upon them the name of influenza cocci. They occur both in chains and in pairs, as well as being scattered singly. They measure one and a half to two micro-millimetres in length, and one micro-millimetre in breadth. These microbes were also found in the secretion from the nose in every instance, but could not be discovered in that from the eye, nor in the blood. They appeared to have no connection with the pus-cells, occurring rather between than within or upon them.

The sputum from cases of ordinary bronchial catarrh was examined at the same time, but did not show these organisms. The only experiment seems to have been the inoculation of guinea-pigs, which failed to produce the symptoms of the disease. Until other observations and positive culture experiments have been made, we must regard the rôle of this new coccus and its pathological properties as still sub-judice.

A PLEA FOR THE SPECIALIST.

Specialism is an established feature of modern medicine. It is something which cannot be cried down, for already, in the face of opposition and distrust, it has steadily increased, and will surely continue to do so. It is not an artificial addition to medicine, but a natural and inevitable development. It has its dangers, against which we can utter warnings ; it has its defects and insufficiencies, which should be pointed out. But to attempt to check its growth would not only be useless, but would work an injury to the profession. It is, perhaps, but fair to say that the principal advances in medical science to-day are being made by specialists, that these gentlemen are, as a rule, more thoroughly educated, more carefully trained, more persistent, industrious, and enthusiastic workers than is the average general practitioner. The specialist chooses for himself a life which involves hard work, the strife of active competition, and late rewards.

Undoubtedly there is danger in specialism, lest it lower the general standard of professional honor and dignity. All quacks are specialists, and alas ! some specialists are quacks. There is danger to the patient, also, in the specialist's losing sight of the man in pedantic investigations of the "case." These are things which medical educators and a wise professional feeling should try to prevent. For they are incidentals, not essentials, of specialism, as the fact that the majority of the leaders of our profession to-day shows.

THE LEGAL VALUE OF EXPERT TESTIMONY.

The question of expert evidence and its value is a perennial one, and a recent statement of a Western court will be of interest. In this case the trial judge had directed that the expert testimony "should be received and weighed with caution." Upon an appeal the higher court said : "We think that such testimony should have been given due and proper weight, and should not have

been 'received and weighed with caution.' In the case of Carter *vs.* Baker, 1 Sawyer, 512, the presiding judge laid down the following rule: 'The testimony of experts is to be considered like any other testimony; it is to be tried by the same tests and receive just as much weight and credit as the jury may deem it entitled to, when viewed in connection with all the circumstances.' We think this is probably as good a general rule as any that could be adopted."

Mr. Lawson, in his work on "Expert and Opinion Evidence," page 240, states the rule as follows: "The testimony of experts is entitled to the same credit; is to be tested by the same rules as are applied to the evidence of other witnesses, and should have weight with the jury according to their opportunities and qualifications, but it is not conclusive. . . . While many courts speak disparagingly of some kind of expert testimony—that with regard to handwriting, for instance—yet we think that all courts hold that the testimony of competent medical experts is entitled to great respect and consideration."

The case was, therefore, reversed on the point of improper instruction in regard to expert testimony, and a new trial granted.

INOCULATION OF TUBERCLE IN THE HUMAN SUBJECT.

THE number of successful experiments made upon the lower animals to demonstrate the inoculability of tuberculosis is so large as to leave no doubt concerning the fact that the disease can in them be so transmitted. But as regards man, the demonstration by experiment is naturally wanting, and although the evidence of clinical experience in favor of the theory of contagion is sufficient to convince most minds, there is, nevertheless, no such overwhelming proof of this assumption as exists in the other case. We do not remember to have seen recorded hitherto any instance of direct inoculation in man that could justly be regarded as a fact beyond all gainsaying. But this missing evidence would seem now to have been supplied by Dr. E. A. Tscherning, of Copenhagen, in a case related by him in the *Hospitals-Tidende* of December 17, 1884. The subject of the report was a young woman, twenty-four years of age, employed as cook in the family of a certain Professor H. She was a strong healthy girl who had never had a suspicion of any scrofulous or tuberculous affection, and who gave an unexceptionable hereditary history free from the slightest taint of tuberculosis. Professor H. died in July of last year of pulmonary phthisis, after an illness of only five or six months' duration. Toward the close of his life the sputum, it is stated, was so loaded with bacilli as to constitute almost a pure culture of these organisms in pus. A few days before her master's death the cook broke a glass which the patient had used to expectorate in, and ran a small sliver into her left hand, receiving a punctured wound on the palmar surface of the first phalanx of the middle finger. Fourteen days later she presented herself at Professor Studsgaard's clinic with what seemed to be a commencing felon. Carbolized compresses were ordered, and at the end of weeks the finger seemed to be better; there had been no suppuration. But at this time a little nodule, scarcely half as large as a pea, was felt in the subcutaneous connective tissue. During the following week this remained stationery in size, but became somewhat tender and was surrounded by an œdematous area. The nodule was now excised, and was found to consist of granular matter lying between the sheath of the tendon and the skin. The wound healed by first intention.

At the beginning of October the patient again presented herself, complaining of pain on flexing the finger. The subcutaneous connective tissue on the palmar surface of the hand, as well as of the affected finger, was swollen, but no distinct tumor on the sheath of the tendon was discoverable. A month later, however, a distinct thickening of the sheath of the tendon was to be felt. Two cubital and two axillary glands were also enlarged. An operation having been decided upon, Professor Studsgaard disarticulated the middle finger at the metacarpo-phalangeal joint, and dissected away the tendon with its thickened sheath as far as the middle of the palm. The swollen glands at the elbow and in the axilla were also removed. Examination showed the sheath of the tendon filled with pale granulations. No pus nor cheesy matter was to be seen, nor was there any disease of the bones or joints of the amputated finger. The granulations, hardened in alcohol and stained with picrocarmine, when placed under the microscope were seen to be composed of tubercles, with, in some cases, central caseous degeneration, numerous large cells, and many beautiful, in part, central giant-cells. The extirpated glands looked to the naked eye as simply hypertrophied, and free from pus or caseous matter. Under the microscope large-celled hyperplasia, and here and there isolated tubercles were found. In every section, either of the sheath of the tendon or of the lymphatic glands, numerous tubercle bacilli were seen lying either in the giant-cells or at the edges of the microscopical points of necrobiosis. The bacilli were usually isolated, but here and there two or three were found together; in many cases they were seen to be provided with so-called spores. These appearances, Dr. Tscherning states, were the same as those observed by him in upward of thirty other cases of localized tuberculosis. Unfortunately there were no dogs at hand upon whom he could observe the effect of inoculation, but the microscopical examination sufficiently established the tubercular nature of the affection. This very interesting case would seem to fill a gap hitherto existing in the study of tuberculosis between the results of experiments upon the lower animals and the evidence afforded by clinical experience in man.

DR. DELAVAN ON THE INTERNATIONAL CONGRESS.

THE social element of large medical bodies is, perforce, apt to remain unwritten, but Dr. D. B. Delavan has done well in breaking the rule and giving, in a small octavo volume, the "Social History of the Eighth International Medical Congress," held in Copenhagen in August of last year. Their Majesties the King and Queen of Denmark were not satisfied with opening the Congress, but received, together with all the royal household at that time in Copenhagen, the delegates in a most sumptuous manner. The unparalleled hospitality of the Scandinavians, the absence of conventionality at their dinners, the happy

ubiquity of their "skaal," or toast of individual recognition at table, all attest the unbounded *bonhomie* of their character.

When our Danish friends respond to our invitation to Washington in 1887, though we have not royal palaces, court jewels, and a court pageantry by way of entertainment, let us not forget that what most interests foreigners in the United States is the marked intellectual individuality of American institutions and American scenery, than which latter there is none grander in the world, and let these be offered as social entertainment to our last year's hosts with true American hospitality.

THE NEW YORK STATE MEDICAL SOCIETY.

The meeting of the New York State Medical Society last week was in some respects a more notable one than usual, for the Society succeeded in coming to an agreement regarding the bill to establish a Board of Medical Examiners—a consummation which should be a subject for much congratulation. Medical legislation in this country has been, and must for some time be, largely experimental and not always satisfactory. Nevertheless, the general principle at which the Society's bill aims is based on good sense and on experience in other lands besides our own.

The number of members present was less than last year, as would be expected. The number of carefully prepared and meritorious papers was, however, somewhat larger than usual, showing that the old Society has lost none of her vigor. The scientific contributions would be more symmetrical, however, if the ophthalmologists did not feel the burden of the duty of paper-reading quite so heavily.

Every year the inquiry is renewed why the State Society holds its meetings in the busiest month of the year, and in a city so full of pneumonia-haunted bedrooms and dyspepsia-making hotels.

THE MADNESS OF McCULLOUGH.

Either the tragedian, Mr. John McCullough is sane and should be so treated, or he is insane and should receive such care as might restore him. At present, his mental condition has become an affair for managerial trickery and newspaper polemics, while the unfortunate sick man himself is subjected to irritations which are anything but curative. It is reported to us, and we believe the report, that Mr. McCullough is in the incipient stage of a grave cerebral disease. Only the most judicious care will ever enable him to act again. This he is plainly not receiving.

THE CHEESE BACILLUS AND CHOLERA.

We read the accounts of Dr. Deneke's discovery (*Deutsche Medizinische Wochenschrift*) in cheese of a bacillus almost absolutely identical in form and mode of growth with the cholera bacillus of Koch. Dr. Deneke made his investigations at the Hygienic Institute at Göttingen. The bacillus which he found in stale cheese is very slightly different morphologically from the cholera bacillus. It will not grow on potatoes and in some other media which favor the cholera bacillus but its development in blood-serum, agar-agar, and gelatine is almost identical with that of the supposed specific bacillus.

Pure cultivations, however, when injected into guinea-pigs were harmless, while similar cultivations of the cholera-bacillus in one case produced choleraic symptoms and death. Dr. Deneke does not think that the cheese bacillus and cholera-bacillus are physiologically identical; but it is apparent that his discovery makes it more difficult to attach a diagnostic value to Koch's micro-organism.

News of the Week.

Dr. E. C. Spitzka has resigned the Chair of Neuro-Anatomy and Physiology at the New York Post Graduate School.

A Death from Nitrous Oxide Gas, administered by a dentist in Paris, is reported.

A Medical Centenarian Dead.—Dr. Christopher Columbus Graham, of Louisville, Ky., died on February 3, 1885. He was one hundred years old last October.

Reappearance of Cholera in Italy.—It is reported that cholera has reappeared at Gaëta, Italy.

A New Modification of the Operation for Resection of the Stomach has been recently devised by Billroth. He cuts the duodenum squarely off and sews up the end. The cancerous part of the stomach is then removed and the resected stomach sewed to the lower end of the duodenum. A successful application of this method has just been made.

Dr. Hutton, of Fergus Falls.—We learn with regret that Dr. Hutton, of Fergus Falls, Minn., whose vigorous presentation of the subject of diphtheria, from a frontiersman's point of view, attracted some attention last year, is himself suffering from the disease. Dr. Hutton is contented with an application of nitrate of silver to the throat, a chlorate of potash gargle, and stimulation.

Orthopædic.—The New York Athletic Club has for its seal a winged foot. Though beautifully proportioned it is undoubtedly a club foot.

Quacks and Medical Women.—We have received from M. Putnam-Jacobi a letter upon this subject, which we regret we have not space to publish in full. Dr. Jacobi contends that the cause of the disproportionate number of uneducated and irregular women-physicians lies in the fact that the larger and better class of medical colleges refuse to admit female students.

Sensory Nerves of the Lungs.—Mr. Elwin F. Beckwith, of Columbus, O., writes us that he has demonstrated the sensory nerves of the lungs with their ganglia and terminations. As the lungs, apart from the bronchial mucous membrane, have no sensory but only excito-reflex nerves, Mr. Beckwith has plainly accomplished a considerable feat.

Symmetrical Gangrene.—A correspondent who asks for the literature of this subject will find an article upon it in the *Boston Medical and Surgical Journal*, January 16, 1879, p. 76.

Non-Restraint in Insane Asylums.—Dr. H. Washburn writes us regarding this subject, and ventures the opinion, based upon his personal experience, that Insane Asylum Superintendents have not changed their views regarding this matter of late, but have come to use restraint less because they have been better supplied with attendants. This theory, however, by no means explains the fact that many Superintendents have openly declared their disbelief in total non-restraint, and that in some of the best equipped asylums cribs and other restraining apparatus are still used. The plain facts are that many Superintendents are too busy with the farm accounts, or too pig-headed to learn what non-restraint can really do, and how practicable a therapeutic measure it is.

Dartmouth Medical College.—The Dean of the College, Dr. C. P. Frost, writes that there is no purpose on the part of Trustees or Faculty to remove the College from its present location. The project was conceived by an outsider.

The Schweninger Scandal has reached public proportions, and the news is cabled that a hot discussion has been excited in the Bundesrath over a proposition to pay the new Professor 3,600 marks.

Schweninger has become the best advertised doctor in Germany, and has, we are told, an enormous practice. In his earlier years, while in Munich, he had a too erotically aggressive affair with a woman, for which he was imprisoned, and subsequently expelled or dropped from the medical societies. The reports now circulated of his experience as a Don Juan, however, have, it is said, made him particularly popular with the ladies.

Klein Mercilessly Annihilates Koch.—A cablegram announces that Dr. Klein read a report of the investigations made in India by Gibbes and himself, before the Royal Society last week. He mercilessly criticised the cholera bacillus theory of Koch.

A candid correspondent of a leading Western medical journal writes: "I do not want your journal, especially if I have to pay for it! With as much respect as I can have for any one engaged as you are, I subscribe myself, etc." Such are the interruptions into the riotous ease of the medical editor's life.

Dr. E. A. Gatchell, of Asheville, N. C., writes: "Following the Appendix to Parkes' Manual I misstated the distance between Aiken and Atlanta, the true distance being 188 miles. By some inadvertence also, in the second mention of the winter precipitation at Asheville, I gave it as 13.5 instead of 9.5 inches; the annual precipitation being, at Asheville, 40.2; at Aiken, 55.0; Atlanta, 62.7; and Jacksonville, 65.5 inches."

Religious Newspapers and Quack Advertisements.—The English medical journals are beginning to call attention to the present extensive prostitution of religious journalism to quackery. The *Lancet* says: "Some of the best friends of religious newspapers, and even of missionary journals, are becoming seriously scandalized at the growth of the advertising of quack medicines in their columns. The feeling of disgust is not confined to the medical profession; nor, we must admit, is the scandal of quack advertisements confined to the class of papers in question. But the scandal is most striking and most unseemly in them. When a man sees in his religious newspaper an advertisement of a man or a medicine as pretending to cure a disease in his child or his wife beyond the bounds of the medical art, the pretension being backed perhaps by a great name, he is apt to yield to the temptation, and when the coarse pretension is refuted by the death of the patient, he has a sense of injury."

New York Polyclinic.—The number of practitioners who have thus far studied in the Polyclinic as members of the class is 463. The attendance for the present session is twenty-five per cent. in excess of any former year.

Medical Society of the State of New York.—On the last page of our report of the proceedings of this Society (February 7, 1885), it was said that "County Societies" were requested to hold their annual meetings "in other than the first three months of the year." It should have read *only within* the first three months—that is, January, February, March. Dr. Low read a paper on "Ovariotomy," etc., not Craniotomy. Dr. Sawyer was unable to attend, and Dr. Jacobi, of New York, presided at the meeting on Wednesday evening. For these and other errors, the telegraph operators must take a share of the ——

Security for Doctors' Bills.—Four physicians of Hart County, Ga., have signed and published a card, stating that all persons desiring professional services who have not heretofore paid their medical bills promptly must give some guarantee that their bills will be paid as they fall due. Tenants who have no real estate or other property which is a good security for the payment of their bills must obtain orders from their landlords, who will become responsible for the payment of all bills made by tenants.

Commissioner Charles F. Peck on Child Labor in New York.—Mr. Peck finds that nearly one-third of the 1,685,100 school-age children in this State do not attend school; that the system of child labor exists in this State in its worst forms; that the compulsory education law of the State is, to all intent and purpose, a dead letter; that the moral and mental conditions of child wage-workers are of a low standard; that the sanitary condition of a large number of the mills and tenement-house factories, in which children are employed, is a disgrace to civilization, and that the proper safeguards to protect employees from accident by machinery, or their lives from jeopardy in case of fire, are sadly insufficient. His remedy is compulsory education.

Voluntary Sanitary Organizations are now the order of the day in this city. Besides the Sanitary League, various Ward Associations are being organized. One of the most active of these is the Tenth Ward Association, which is starting a sanitary lodging-house where the tramp is obliged to wash and sleep in a night-shirt.

Dr. Theodore R. Varick will read a paper on "The Protective Treatment of Wounds," at the next meeting of the New York County Medical Association, on Monday evening, February 16th, at the College of Physicians and Surgeons.

Presbyterian Hospital Clinics.—Regular Saturday clinics will be held at the Presbyterian Hospital, Seventieth Street and Madison Avenue, commencing at 2.30 o'clock. The surgical clinic will be in charge of Dr. George F. Shrady, and the medical clinic will be conducted by Dr. A. H. Smith. Advanced students and practitioners are invited.

The British Army in Egypt under General Wolseley is suffering from a severe type of typhoid fever. The etiology of the disease is obscure, as the water used is good and there are no unsanitary cities or towns where it could be contracted.

Misuse of Official Position.—We have before us the engraved copy of a letter from the Commissioner of Health, of Baltimore, certifying to the merits of a secret cough nostrum. When a physician lends his name to such purposes, he not only does public injury, but he destroys his professional standing. We can but hope that Dr. Stewart has been himself imposed upon.

The Corset.—Dr. Samuel W. Francis says that if women spelt corset with a "P" (Corpset!) they would live longer and there would be fewer physicians.

Free Medicine at Atlantic City.—We are credibly informed that it is a common practice among the physicians of the well-known health resort, Atlantic City, N. J., to treat the boarding-house and hotel-keepers with their families free of charge on the very distinct understanding that in the summer their guests will be sent to the accommodating physician. The competition is so brisk that this practice has reached unhealthy limits. It is not elevating and smacks unpleasantly of pure business. We trust that the County Society will examine into the matter and try to correct the abuse.

Mercy Hospital, Big Rapids, Mich.—It is a question whether, in publicly advertising the needs of this apparently excellent hospital, it is necessary or in good taste for the medical staff to figure so largely as they do. The hospital has one hundred beds and treated seven hundred and forty patients last year.

The Homœopathic Medical College for Women in New York City.—We are asked to correct a statement which we made regarding the "shorter and cheaper course" which the above College has heretofore offered, as compared with that of the regular medical school. Our statement was correct for the past, but we take pleasure in stating that with the present year the course in question has been made compulsory for three years. We trust that this may help to lessen the number of women quacks, but we very much doubt it. It may be laid down as a general rule that whenever a poor medical college feels particularly poor, it opens its doors to women. It is applauded as liberal and gets a few more students.

"English as She is Spoke."—The following choice specimen of English is said to have been copied, *verbatim et literatim*, from the notes of a clinical lecture made by a student in one of our medical colleges: "Straned himself and spit of a brite red collor. Have you had any feaver or nite swets? No. Very little expanshun of scapular on rite. Fisical examenashun, exagerated breading. herd fricton sounds. Herd snores valves. Fibrous teases. Cant be cured but can be sent to mexico."

New York Infant Asylum.—Dr. E. C. Wendt has been appointed pathologist, with a seat on the Medical Board, to the Maternity and House of Reception, *vice* Dr. Wm. H. Welch, resigned.

Bacilli in Chains. — A correspondent humorously writes: "I am delighted to find in The Medical Record of to-day, p. 128, second column, that '*Micrococci in chains*' have been found! I hope they will be *kept* in chains and for a long time. If the other silly bacilli could share the same fate, how nice it would be! I suppose we shall have bacilli soon for all the different kinds of fractures and dislocations, and also for color blindness? What a beautiful sight, all these different bacilli, on *exhibition*, each having his own little *cell*. Even when the dear things are dead, they would make such a nice pretty collection, stuffed and labelled, and placed in glass cages! The dear little things!"

Druggists as Lieutenants.—A bill has been introduced into the House of Representatives (H. R. 8017) providing that the apothecaries in the army and navy shall receive a commission, those of the army to have the relative rank of second lieutenant, those of the navy to have the relative rank of ensign. These commissioned pharmaceutists are not to be in the line of promotion. The scheme of the bill is neither a necessary nor a wise one, and it will undoubtedly fail.

The Legal Status of Antiseptic Surgery.—In Germany, according to the Philadelphia *Medical Times*, the papers report a recent case where a physician used the old methods of treating wounds instead of the modern antiseptic dressings, and the patient died under circumstances making it probable that if a different treatment had been adopted his life would have been saved. The physician was sued for malpractice, and convicted, the court holding that "every practitioner should keep himself informed on the accomplished progress of science, and have an exact knowledge of modern systems of treatment."

A Hospital in the Adirondacks.—A correspondent of the *Boston Medical and Surgical Journal* writes that there has been established a Sanitarium at Saranac village in the Adirondacks. It is intended for the poorer class of consumptives, and the sum of three dollars a week is charged for board. The remaining expense is to be made up by the contributions of charitable people.

The Inventor of the Hypodermic Syringe, Dr. Wood, died recently at his residence in Edinburgh.

State Medical Examiners in Pennsylvania.—The bill for the creation of a State Board of Medical Examiners and Licensers, which resembles somewhat the Illinois bill, has been considered by both the Philadelphia County Medical Societies (regular and homœopathic). It has not been fully approved by either of them, the principal difficulty being in regard to the representations of the different schools of practice on the Board. Several of the other County Societies of the State have approved the bill.

Drs. S. Weir Mitchell, Charles K. Mills, and H. C. Wood have been appointed Consulting Physicians to the Insane Department of the Philadelphia Hospital.

American Medical Diplomas for the English.—The *Hospital Gazette and Students' Journal* is authority for the following extraordinary statement: "The authorities of the University of Vermont, United States, have announced that they will grant the M.D. degree

to British registered medical practitioners of good standing who pass a satisfactory examination in medicine, surgery, and midwifery. No residence is necessary, and the examination may be passed in three days. The fee for the examination is only £6. The first examination under these regulations will take place in June next, and I have no doubt that a goodly number of English practitioners will be induced to take a trip to the States in order to obtain the legal right to assume the title 'M.D.' Hitherto Brussels has enjoyed almost a monopoly in granting the M.D. to English practitioners, but in future it will find Vermont a formidable competitor for the English guineas." We believe that friends of the college in question will regret that it has gone into a purely money-making business like the above.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

Low Temperature in Disease.—Extremely low temperatures are met with under several conditions: Drunkenness, with exposure, illustrated by the well-authenticated case of Renicke, in which recovery took place after a temperature of 76° F. In mania (particularly of old people), in melancholia, and in progressive paresis, temperatures as low as 74⅘° F. have been recorded. In injuries and disease of the cervical part of the cord a decided reduction has been noted, although more frequently there is an elevation of temperature. The lowest rectal temperature on record is 73⅖° F., in a case of limited hemorrhage into the medulla. The man lived twenty-four hours after, and the temperature did not rise above 82⅖° F.—*Canada Medical and Surgical Journal*, November, 1884.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 5, 1885.

FORDYCE BARKER, M.D., LL.D. (EDIN.), PRESIDENT, IN THE CHAIR.

THE evening was devoted to the addresses of the retiring and of the incoming Presidents. DR. BARKER's valedictory has already appeared in the columns of THE RECORD for February 7th, and the inaugural address of DR. A. JACOBI appears in the columns of this number.

There were seated upon the platform: Weir Mitchell, M.D., and Theophilus Parvin, M.D., LL.D., of Philadelphia; John S. Billings, M.D., LL.D. (Edin.), of Washington; George B. Shattuck, M.D., and James R. Chadwick, M.D., of Boston; James Anderson, M.D., ex-President, and Alfred C. Post, M.D., LL.D.

At the close of Dr. Jacobi's address, DR. CHADWICK presented a photograph of Oliver Wendell Holmes, accompanied by the following letter addressed to Dr. Barker:

AN OPEN LETTER.

BOSTON, February 4, 1885.

MY DEAR DR. BARKER: You must allow me to join my best wishes to those of the friends who will surround you as you take leave of the office which you have filled so ably and happily.

I trust that you have not forgotten the day when you were with us at the opening of our Boston Medical Library. I know full well that we remember your presence, and how much it added to the pleasure of the occasion. Our Library Association, I hardly need tell you, has proved eminently successful—I want to say because you smiled upon its birth, but I dare not, for you have smiled upon a great many births, not every one of which, perhaps, has had the good fortune of the infant institution which you joined us in welcoming.

You may have learned some of our secrets during that visit, who knows? There are sparks of intelligence still left among us. At any rate, ever since you left Boston we have kept an eye upon you. As soon as it was learned that you had been spending some little time here, you were made President of the New York Academy of Medicine. As soon as you got back, for *some* reason, the Academy took a new start and has been flourishing ever since. All my informants agree about the fact, and they add that it is due to your own faithful administration and energetic efforts.

We of Boston congratulate our brethren of New York that they have had the great advantage of your services during these last eventful years. The gratitude of the medical profession will keep alive the memory of its benefactors. We must trust the future for its *vis a fronte*, but in the broadest and loftiest period of progress the leaders will look back to the days of up-hill work when you, our honored friend, lent all your vigor to that *vis a tergo* which they will feel pressing them forward to larger and higher achievements.

Pardon me for addressing this open letter to you. You can retire "to blush unseen," while some friend is reading it, if it is thought worthy of that honor.

Always faithfully yours,

OLIVER WENDELL HOLMES.

To FORDYCE BARKER, M.D.,
President of the New York Academy of Medicine.

THE DISCOVERER OF DIAPEDESIS.—The discovery of the diapedesis of blood-corpuscles has always been attributed to the late Professor Cohnheim. M. Cornil recently put in a claim for a French scientist, M. Dutrochet, who described this process in his work on the microscopic structure of animals and vegetables published in 1824.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 14, 1885.

(Concluded from page 164).

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. W. M. CARPENTER presented, in behalf of a candidate, a specimen of *cancer of the intestine*.

It was referred to the Committee on Microscopy.

DR. W. GILL WYLIE presented

ELEVEN SPECIMENS REMOVED BY TAIT'S OPERATION,

with a brief history of fourteen cases. [See page 161.]

DR. PUTNAM-JACOBI referred to a case in which the patient was operated upon in Philadelphia, for dysmenorrhœa, and one ovary removed. She recovered from the operation rapidly, but her suffering was precisely the same as before it was performed.

DR. E. C. WENDT had seen three or four cases of hysteria, supposed to be of ovarian origin, in which the ovaries with the tubes were removed, but without affording relief in a single instance. In each case there was cystic degeneration of the ovaries. As for the matter of the occurrence of small cysts in the ovaries, it was so frequent that he did not think it was of much pathological significance. Cystic degeneration of the ovaries, in animals, was exceedingly common.

DR. PUTNAM-JACOBI regarded the accompanying conditions, inflammatory in character, as more important than the cystic degeneration of the ovaries.

DR. WENDT was of the same opinion.

DR. WYLIE said that in these cases the cysts were much more numerous than usual; so much so that the entire ovary was commonly occupied by cysts. He had not yet seen a case of marked hystero-epilepsy in which this operation had been performed, and the ovaries were not especially cystic, when compared with the average cystic degeneration of these organs; whereas, in cases in which there was no hystero-epilepsy or hysteria, there were no cysts.

In most of the cases he had given, the patients were operated upon for the relief of pain, and while, without a single exception, there was evidence of old pelvic peritonitis, he regarded it as secondary to the disease of the tubes.

DR. COE regarded it as important to notice whether the cysts were peripheral or central. If simply central, it did not signify very much; but if the ovary was cystic throughout, that fact was very good evidence that there had been such an increase of interstitial tissue that the cysts had not been able to reach the periphery, and had been confined to the central part of the organ. It was this condition only which, strictly speaking, should be called cystic degeneration of the ovaries.

SARCOMA OF THE LOWER JAW.

DR. JOHN A. WYETH presented the patient upon whom he had operated and removed the specimen presented to the Society at the last stated meeting. [See MEDICAL RECORD, January 25, 1885, p. 111.]

No interdental apparatus had been worn by the patient, and yet the jaw was on a direct line.

The Society then went into executive session.

EARLY RISING FOR LITERARY WORKERS.—Rev. Mr Haweis, an English writer of some note, says: "Morning literary work is usually characterized by freshness, continuity, grasp, and vigor; night-work by fever, excitement, and less condensation. This I believe to be the rule; and with exceptions, in speaking thus generally, it is of course impossible to deal." If this view is true, and we are inclined to believe it is, we can recommend doctors to adopt it. It would be a desirable thing to secure more "continuity, grasp, and condensation" for medical writings.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DEBATE ON BACILLI AND THE PATHOLOGY OF PHTHISIS AT THE MEDICO-CHIRURGICAL SOCIETY—SPEECHES BY SIR ANDREW CLARK, DRS. GREEN, WILSON FOX, AND MOSCOW—DEATH OF DR. BAXTER.

LONDON, January 17, 1885.

A VERY interesting discussion on the tubercle bacillus and the pathology of phthisis is at present going on at the Medico-Chirurgical Society. It was opened at the beginning of December by Dr. Percy Kidd, who read a paper on the "Distribution of the Tubercle Bacilli in the Lesions of Phthisis." Dr. Kidd supported Koch's views on the whole.

In the discussion which ensued Dr. Creighton questioned the validity of Koch's method, which was defended by the next speaker, Dr. Theodore Williams.

Sir Andrew Clark said he could not concur in the statement that the bacillus was sufficient to explain all the lesions of phthisis. He defined phthisis as the assemblage and progression of states associated with or dependent upon ulcerative or suppurative destruction of more or less circumscribed non-malignant deposits or consolidations of the lungs. Under this definition would also fall chronic interstitial pneumonia or fibroid phthisis, for ulcerative or suppurative destruction of tissue occurred, together with symptoms which could not be distinguished from those of ordinary phthisis, and yet in the lesions no bacilli could be found. No bacilli were found in some cases of acute miliary tuberculosis; and, further, in some cases no bacilli were to be detected until softening had taken place. These facts led him to doubt the casual relation of the bacilli to phthisis.

The discussion was resumed on Tuesday last, January 13th. Dr. Kidd's specimens were again on view, and speeches were made by Drs. Hermann Weber, T. Henry Green, Wilson Fox, and Moxon. Mr. Watson Cheyne also spoke and gave a very instructive demonstration of the bacilli of tubercle, and the methods of cultivating them. Numerous specimens and photographs were also shown by Mr. Watson Cheyne.

Speaking broadly, it may be said that at the debate of last Tuesday all the speakers avowed more or less allegiance to Koch's views—some almost unreservedly.

Dr. T. Henry Green said Dr. Kidd's paper was another addition to the facts already in our possession which tended to show that bacilli were present in all those pulmonary lesions we regard as phthisical, and absent in those which are not phthisical. He suggested that we might define clinical pulmonary phthisis as including all cases of pulmonary consolidation in which the three following characters were present: 1, Distribution more or less apical; 2, tendency to undergo softening and disintegration; 3, possession of infective properties and hence of a tendency to spread.

This definition excluded many chronic lung diseases sometimes considered phthisical, but he thought this clinical and pathological distinction between phthisical and non-phthisical forms of lung disease was justifiable apart from any question of bacilli. It was also, he believed, in complete accord with Koch's discovery. The unity of phthisis seemed to be established by the observations of those who had worked on the subject. For his part, he doubted the existence of non-tubercular apical consolidations.

Dr. Wilson Fox said the characteristic bacteridia had been found in nearly every form of tubercle, and in pus proceeding from tubercle, and so far the evidence in favor of Koch's views was strongly confirmatory. The failure to find bacteridia in some cases would not destroy the phthisical nature of the disease, for one would not expect to find the active agent in all cases. Leyden had pointed out that the fallacies of the histology of the sputa in relation to the bacilli were more numerous than surrounded the older methods of investigation. Tubercle was an inoculable disease and almost nothing else is so inoculable. Cheyne and Dawson Williams had proved by experiments that tuberculosis could only be obtained by the inoculation of specific material. Diseases due to bacteridia were mostly contagious, but it would be a grave step to assert that tubercle also was contagious. The evidence to prove that tubercle was contagious in man was of the most difficult kind. Dr. Wilson Fox said he thought that, although the evidence in favor of Koch's views was so strong, yet looking to the constant change in our views on phthisis, and seeing how the pathology of tuberculosis has biennially, triennially, or quinquennially been swayed by histological dogmata, it would be well if we waited before definitely accepting all that the new views implied.

Dr. Moxon said he had long held the opinion that all phthisis was the same disease, and had done so from anatomical considerations. He had long observed that tubercle was always spherical, and thought there must be some reason for this. In masses of tuberculous growth, the periphery was living and the centre was dead. He had compared them to fairy rings though he did not mean much by the term; it was almost poetical. He thought we had now revealed the factor which makes phthisis one and the same thing. He believed Koch was right. But nevertheless we could not expect to always find a bacillus in the sputum at any stage and in every case of phthisis. The life of a tubercle was not equal in duration to that of a case of phthisis. Three months was about the duration of the life of a tubercle; that of phthisis might be twenty years. He said he had come to the conclusion that phthisis was a compendium of every disease in pulmonary pathology excluding cancer and including embolism. Pregnancy, heart disease, and, in fact, all venous conditions disfavored phthisis. Hence tubercle did not usually exist in the region of the Pacchionian bodies, never occurred in the liver, but was common at the base of the brain. We could explain much by considering the delicate conditions requisite for the growth of the bacilli. The life of a parasite was not so easy as it seemed at first sight to be. The aphis of a rose did not live in a westerly wind. So, though we might catch tubercle bacilli at every moment, yet a favorable soil might be wanting.

Last week I recorded the death of an eminent physician, Dr. Herbert Davies. I regret to have now to register that of Dr. Buchanan Baxter. Dr. Baxter was not so well known as Dr. Davies, and cannot be said to have attained equal eminence, but he was as yet only a young man, comparatively speaking, and there is every prospect that he might have made a considerable mark had death not taken him from us. A distinguished graduate of the London University, he became Assistant Physician to Kings College Hospital, and succeeded Dr. Garrod as Professor of Materia Medica. He also became examiner in the latter subject at the University, and edited Dr. Garrod's well-known manual. He also edited "Rindfleisch" for the New Sydenham Society. He won considerable repute some ten years since by writing some special scientific reports for the Privy Council.

TOLERANCE OF LARGE DOSES OF POTASSIUM IODIDE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I report the following case as an instance of large doses of the iodide of potash continued for four months, the patient thriving on the medicine, and gaining in flesh and strength daily. The case is peculiar in other respects also, in that, although there was no history of syphilis, and scarcely a symptom, still the rapidity with which the lesions disappeared under specific treatment appeared almost miraculous. Mrs. W—— applied for treatment

for skin disease on July 3, 1884. History as follows: American; aged fifty-four; married to second husband; four children living, and all healthy; three by first husband, and one by second. Patient is a short, spare woman, seemingly quite emaciated and weakened by disease. Twelve years ago she began to be afflicted with the disease for which she applied for treatment, and for which she has been treated off and on ever since, at times receiving some benefit, but more often none. At the time stated, twelve years ago, abscesses, simulating furuncles at their commencement, began to form on her lower legs over tibia, and on her chest over sternum. These abscesses pursued a very slow course, it sometimes (and generally) being months before they opened, and as many months and more before the discharging sinuses left by them completely healed. During their evolution there was great pain, and even when they had opened, and a free exit was formed for the pus, the pain still continued, more especially at night. Six years after their first appearance on her legs and chest, the same peculiar abscesses made their appearance on her forehead, and not only increased her discomfort by the greater pain produced by them in this situation, but by the disfigurement compelled her to live entirely within doors. On July 3d, when I first saw Mrs. W——, there were visible two discharging sinuses on right leg over tibia, near the ankle; two ulcers on forehead, very close to margin of the hair; and one *cold* abscess on crown of head, which differed from previous abscesses by so far having given rise to no pain; besides numerous and depressed scars on both legs over tibia, on chest over sternum, and on forehead; in fact the latter had the appearance of one large cicatrix, the abscesses having been so numerous that scarcely a healthy piece of integument was to be detected. Upon further examination found heart and lungs normal; urine, sp. gr. 1.011, acid, pale, with no sediment, and a slight trace of sugar by bismuth test; appetite poor; bowels constipated. Patient stated that she passed large quantities of urine, especially at night. Reserving my diagnosis, I put her upon Wyeth's elix. iron, quinine, and strychnine before meals, and tr. valerian after meals; morph. sulph., q. s. for relief of pain. On July 17th patient had quite a severe attack of cholera morbus, and treatment ceased until July 23d, with the exception of the application of Martin's rubber bandage, which, thinking it might possibly ease the pain, I had ordered on July 14th. On July 25th, finding there was great pain on pressure over the shins, and the hypersecretion of urine having ceased (sp. gr. 1.020, acid, no albumen, no sugar), I decided upon a radical change in the treatment, and began the administration of the iodide of potash in increasing doses. I ordered for her the following preparation:

℞. Potass. iod..... ʒ j.
Aquæ.....q. s. ad. f ℥ j.

Beginning with eight drops, representing grs. viij. of the iodide, t. i. d., I increased the dose by one drop (gr. j.) daily, until she reached the maximum dose of thirty drops, representing half a drachm of the potassium iodide, after each meal (t. i. d), in half a glass of water. On August 2d Mrs. W—— was taking grs. xvj., t. i. d., and the pain in limbs had to a large extent ceased; the abscess on occiput had inflamed, and was slightly painful. On August 3 I opened this abscess, evacuating probably half an ounce of thick, creamy pus, and dressing with carbolized cotton (absorbent) compress. On August 13th, ten days after the opening of this abscess, and nineteen days after the first dose of the iodide was taken (grs. xx. being the regular dose at this date), all pain had ceased, the abscess on the crown of head had stopped discharging and was healed, and sinuses on leg likewise. The only remaining lesions were the two ulcers on forehead. Believing that these were prevented from cicatrizing by the irritation produced by Mrs. W's—— bang, I prescribed ung. zinc. oxid., to be applied on cotton; and, on August 20th, I found that I was right, and that they too had healed. Mrs. W—— now continued taking her regular dose of twenty grains of iodide of potash thrice daily (with the addition of a dessertspoonful of Wyeth's elixir of gentian, with the tincture of the chloride of iron, before meals, from August 20th to November 1st, occasionally, and for two or three weeks at a time, increasing the dose to ʒ ss. t. i. d. On November 1st Mrs. W——, having had no symptom nor manifestation of her previous disease since August 20th, was discharged, to all intents and purposes, cured. I, however, advised her to continue the iodide for another month, which she has done. On December 1st I gave her a prescription for pil. hydrarg. bichloride (gr. $\frac{1}{10}$), to be taken after meals, and continued the tonic before meals. Patient has now gone South to spend the winter months.

This is an instance, most positively, of the toleration of large doses of the iodide of potash, an average daily dose of one drachm being taken for a period of four months, with no symptom of gastric irritation, but, on the contrary, the appetite improving, bowels becoming regular, and patient rapidly gaining flesh and strength. My diagnosis, at first reserved, is still reserved—so far, at least, as regards *naming* the disease; and if any of my professional brethren are familiar with a similar complaint, and can *name* it, they would confer a favor by addressing me.

Mahlon Hutchinson, M.D.
Chicago, Ill.

THE TRUE "POISON IN THE COFFEE-CUP."

To the Editor of The Medical Record.

Sir: Some few months ago the papers throughout the country published an article headed "Poison in the Coffee-Cup" referring to the polishing and coloring of coffee, our "Board of Health" claiming that the material used to give the coffee a bright green appearance contained enough poison to make the so-colored coffee injurious. Those connected with the coffee trade, however, knew that a "mountain was being made from a mole-hill," and that a much greater evil was being carried on without the interference of the health officers in the sale of what is known in trade parlance as "poor skimmings."

"Skimmings" coffee is that which has been damaged—and decayed Java coffee is usually brought here in sailing vessels taking a voyage of from three to four months, during which time the coffee goes through a sweating process, which gives it the rich brown color so much sought after. But during this process the steam arising from the coffee condenses and drips on parts of the coffee, which, in consequence, becomes decayed. On arrival at port this is separated, put into packages, and called "Java skimmings."

Similar damage is also often caused by sea-water, especially on Rio and other coffees brought by steamer. I send you with this a sample from one hundred bags of Rio "skimmings" sold last Friday by a leading auction house for three-fourths of a cent per pound. You will notice that the berry is perfectly decayed, not a particle of it being sound, and that the odor is very offensive. Three years ago the steamer Pliny, from Rio, with a cargo of over thirty thousand bags of coffee was wrecked on Deal Beach, N. J. Thousands of bags of decayed coffee were gathered from the beach and sold on this market.

The "skimmings," when dried, are mixed with sound coffee and sold mostly to the poorer classes. There can be no doubt that a much greater evil is done by the sale of this decayed coffee than by the sale of polished coffee, which is mostly a Rio coffee and used West and South, but seldom in our city. * * *

New York City, January 20, 1885.

[We have examined a package of these "skimmings." They are mouldy, discolored, and ill-smelling.—Ed.]

New Instruments.

REMARKS ON HÆMOSTATIC FORCEPS.

By ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL, ETC.

In the endeavor to render bloodless, or comparatively so, operations in portions of the body to which Esmarch's elastic bandage cannot be applied, and particularly in the neck, where often difficult and careful dissection is required, a marked improvement is to be seen in the surgery of the present day. The removal of a tumor of the neck overlying the vessels and nerves at the upper or lower part of this region, or even of the enlarged thyroid gland with its numerous thin-walled veins, can be accomplished nowadays with not only the saving of blood but without the

Fig. 1.—Billroth's Forceps.

obscuration resulting from the general outpouring from small vessels, which in previous times were allowed to check themselves by their own contraction and plugging.

By using a large incision and by keeping the wound free from blood the favorable progress of a difficult operation is much enhanced. To accomplish this, no sooner does a vessel spirt or bleed freely than a hæmostatic forceps is applied to it by the surgeon or his assistant. If, as is often the case in the deeper dissections, an artery or vein is recognized, it may be seized by the forceps, and then divided between there and the end; if of a

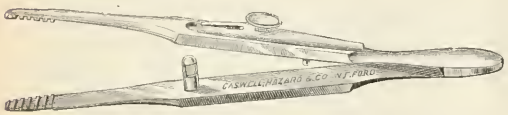

Fig. 2.—Esmarch's Forceps.

large vessel, tied immediately, or, as is much better, the vessel may be tied with two ligatures and cut between them. Generally as each vessel is caught by the forceps, or clamps as they are also called, the instrument is either allowed to hang in the wound, or is held aside by an assistant. When there are so many of such clamps in the wound as to hinder freedom of action the vessels are tied, still held by the clamps, with catgut, when the forceps are released, otherwise the ligation of the vessels is postponed until the operation is completed. Some surgeons, as Spencer Wells, will have their ring-handled clamps so constructed as to give at least twenty-five pounds pressure (whence their name force-pressure forceps), with the in-

Fig. 3.—Hahn's Forceps.

tention of obviating the use of any subsequent ligature, but in practice the failures to do this more than equal the successes. Hence most operators, instead of disengaging the clamps to see if the bleeding will continue, will forthwith proceed to apply the catgut ligature to all the points that have been seized as a more speedy and blood-saving procedure. Of the variety of such forceps to be recommended, experience has shown that the several kinds herewith represented are the most serviceable.

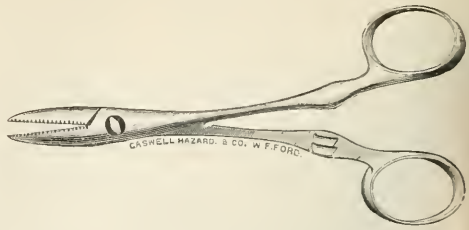

Fig. 4.—Tait's Forceps.

They are of two shapes—Figs. 1, 2, and 3 are patterned after the ordinary forceps, and have strongly marked serrated teeth and sliding catches to hold the grasp when made. Billroth's are the lightest and are usually made of nickeled steel, as are all the others save Esmarch's, which are of German silver and therefore a little heavier. They, however, do not so readily tarnish as the others. Of the two forceps with the sliding catches I prefer those of Esmarch; but the objection applies to both of them, and also to the narrow or sharp-ended ring-handled ones of Pean and Spencer Wells, that it is not always safe to

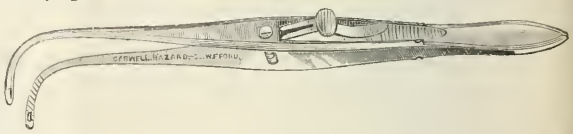

Fig. 5.—Weir's Forceps.

tie a vessel when caught by such forceps. Where the artery, for example, is near enough to the edge of the wound to allow the point of the forceps to be lifted a little from the cut surface by direct traction, or better still by tilting the forceps strongly to one side, the ligature can readily be applied; but when the vessel caught is deep in a wound, the forceps known as Hahn's or Tait's, Figs. 3 and 4, are the best. Their rounded ends completely prevent the ligature being caught in the forceps. These are therefore to be recommended for general use. A further point worthy of note in all these forceps is that all the slides or catches are readily de-

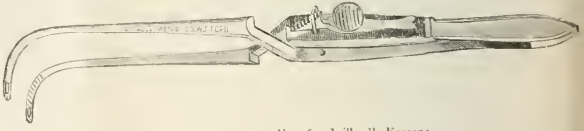

Fig. 6.—Juillard's Forceps.

tached for cleansing; this is separately shown in Fig. 3. In Tait's forceps the blades come apart on wide expansion. In certain cases where the depth of the wound or other reasons forbid the application of the ligature, the forceps can be left *in situ* for several days, covered by the final antiseptic dressing. This expedient is more likely to be resorted to in rectal and uterine operations.

Two other forceps, Figs. 5 and 6, are also presented as particularly serviceable, not as clamps but as facilitating the carrying of ligatures around deep vessels which are to be divided between two ligatures. They are, in fact, an aneurism needle and a forceps combined. I have for several years used one with great satisfaction, not always threading it but more often grasping the double ligature, wriggling the forceps under the vessel, then seizing the ligature, withdrawing the forceps and tying the vessel as desired. Julliard, the distinguished surgeon of Geneva, in his large experience in the removal of bronchoceles found

a somewhat similar instrument, Fig. 6, of great service. It works with an action the reverse of mine. When untouched it remains closed: it can, however, be held open at any point by a graduated ratchet, which is occasionally an advantage.

I have not intended to present all the different forms of hæmostatic forceps, but those which observation and experience have shown to be the best, not only in my own hands but in those whom I have seen use such at home and abroad. To those, too, who are familiar with hospital surgery there is nothing of novelty in the points here made, but to the general practitioner it is believed the subject will be of interest.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 1, 1885, to February 7, 1885.

WATERS, WILLIAM E., Major and Surgeon. Granted leave of absence for one month. S. O. 24, Department of the East, January 31, 1885.

WILSON, WILLIAM J., Captain and Assistant Surgeon. Ordered for duty as Post Surgeon, Fort Preble, Me. S. O. 27, Department of the East, February 5, 1885.

WOODRUFF, EVRE, Captain and Assistant Surgeon. Ordered from Willet's Point, New York Harbor, to Department of Dakota.

TAYLOR, MARCUS E., Captain and Assistant Surgeon. Ordered to Department of the Missouri. S. O. 30, A. G. O., February 5, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 7, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.

February 7, 1885	0	1	15	7	31	26	0	0

NOTES ON THE CLIMATES OF NASSAU, GEORGIA, AND FLORIDA.—Dr. J. W. Dart, formerly of this city, writes us from Jacksonville, Fla., under date of January 3d: "Supposing," he says, "that a patient desires to get into a country where the months of December and January are like that of July in New York City and vicinity, he cannot find it short of the Bahama Islands (Nassau, N. P.). In Georgia, the cold lowers the thermometer during these months below 0°, at times. It has been 13° F. this winter there already. The temperature of Florida rarely goes below 32° F., and as Key West is approached it rarely goes lower than 44° F. Frosts are said to have occurred even below the so-called 'frost line,' at the latitude 29°, near Indian River, on east, and Pampa, on west, in Florida, so that there is no immunity from an occasional frost until below latitude 25° (KeyWest, lat. 25°), and this is about the location of the Bahamas. Last winter frosts occurred in the northern part of Florida. When it was 4° F. in New York City, last winter, it was 22° F. in Mobile, Ala. At Nassau, on the Bahama Islands, the heat ranges from 70° F. up, and is about the same in January as in July. It is said to be cool enough in the shade almost any time. The society there is sometimes poor, but a delightful summer climate and prices no higher than those of Florida are attained. The changes which occur in the climate are very trifling. Gainesville, Fla., is situated on the high ground of the State, yet but little high ground is in the State of Florida. If a patient desires to secure summer weather, let him go first to Nassau and stay there December and January, and then go to Florida, and go north gradually, according to season. Nassau can be reached by the Ward Line of steamers. Fare, $95, round trip from New York, including meals, and $70 from St. Augustine, Fla. A four or five days' sail from New York is to be thought of in the case, and a one or two days' sail from St. Augustine. Nassau is the nearest place for this climate from New York, and the most reliable for the invalid seeking absolute summer weather and slight changes of heat and cold. The island of New Providence is built upon coral and lime, and rapidly absorbs moisture (the *Nassau Almanac* gives full particulars of the city of Nassau). Population about 10,000. A schooner sometimes sails from Jacksonville, Fla.; fare, $20; and also one from Key West. It can be reached also from Cedar Keys. The *Florida Annual* for 1885, published at 140 Nassau Street, New York, gives a good description of Florida and its climate. Mr. Barbour has written a good book on Florida. Florida, in the region of Jacksonville, is damp during December, and January a part of the time, yet preferable principally because it is a city. New York papers reach here about one day late. There is a theatre here (Park Theatre), and several large hotels. Its population is from 7,000 to 13,000, or perhaps more, as it has a large floating population in winter. The trees are all green on this (January 3d) day of writing."

IS IRON GIVEN ALONE OF ANY THERAPEUTIC VALUE?—Dr. S. Bradbury, of Oldtown, Me., lays down a proposition which strikes at the very foundation of our therapeutics. He writes: "I was very much interested in one of your last editorials on 'The Assimilation of Iron,' as I have contended with my fellow-physicians, for the last ten years at least, that iron as given to patients for anæmia has not the slightest effect. I had come to this conclusion for the following reason, namely, *when tried strictly on its own merits, I never could see any results from iron.* Of course, used with quinine, with air and exercise, the anæmic patient would improve, but really, did not the great reputation of iron spring from *theory* instead of from *experience?*"

PREVALENCE OF CANCER.—Forty years ago, Mr. Thomas Wilkinson King drew the following results from some one thousand *post-mortem* examinations performed at Guy's Hospital: "Of all females who die about forty-four years of age, nearly one-half have cancers; of males, one-eighth. Of males above sixty-five, one-fifth of all who die are cancerous."

AMORPHOUS BORATE OF QUININE.—A number of successful experiments with this preparation have recently been made in the medical clinic of Bonn. It appears under the form of an amber-colored crystalline powder, of a not unpleasant odor, of a bitter taste, not so intense, however, as that of the muriate, and soluble in an equal quantity of water. Drs. Finkler and Prior state that this preparation of quinine is much better tolerated, even by the most irritable stomach, than any of the other salts. It has acted well in typhoid fever, septicæmia, pneumonia, phthisis, and in one case of periodical neuralgia. In every case its action was in no way inferior to that of the sulphate or the muriate of quinine. It seems also to produce less ringing in the ears.—*Rivista Internazionale di Medicina e Chirurgia*, November, 1884.

Riots of Students in Madrid.—The *Revista Médica de Sevilla* contains an account of the origin of the students' riots occurring recently in Madrid. It seems that one of the professors, Sr. Morayta, was excommunicated by the Bishop of Avilla on account of some heretical opinions expressed in one of his lectures. A protest against these opinions was drawn up and presented to the students for their signatures. A few signed the paper, but the majority refused to do so, and proceeded to get up a counter-demonstration supporting the excommunicated professor. Numbers of the liberal students marched to the house of Sr. Morayta and cheered him, denouncing the action of his opponents. When the demonstration became a little too noisy, the crowd was dispersed by the police. The students then returned to the University and collected in crowds in the streets, shouting and denouncing the conduct of the police. Upon a second attempt being made to disperse them, they resisted, and became riotous. It would appear that the police acted too hastily, and had they been a little less intemperate in their zeal, the students would have expended their efforts in shouting, and bloodshed would have been avoided.

The Pathogenesis of Cholera.—We find in the *Rivista Internazionale di Medicina e Chirurgia* for November, 1884, a short communication from Drs. Ceci and Klebs regarding their joint investigations into the nature of cholera. They were unable always to find the comma-bacillus in the intestines and in the discharges of cholera patients, hence they conclude that, whatever may be its genetic importance, its diagnostic value is at least doubtful. They have confirmed the opinion expressed in The Record last summer, that the comma-bacillus is really but a form of spirillum. It was found that when the choleraic discharges were left in ordinary temperatures for three or four days, there was developed a pure culture of spirilla, some of which were of the extraordinary length of ten, twenty, or thirty coils. At another time a number of spirilla were seen in the process of division into five or six comma-bacilli at one extremity, while at the other they remained unbroken. No spores were ever observed in the spirilla. As a result of their investigations, the authors conclude that in Asiatic cholera there is probably produced some substance which attacks the cellular protoplasm; and this substance, formed perhaps through the action of the spirilla in the intestines, is reabsorbed. When it is absorbed in dilute form, coming in contact with the tissues, it causes an atrophic condition (of the spleen, liver, cutaneous tissues, etc.); when concentrated, it leads directly to necrosis of the parts. They seem to regard this substance, whatever it may be, as the true *materies morbi*, and look upon the comma-bacillus or spirillum as of less interest. Indeed, they do not regard this as characteristic of cholera. Ceci asserts that the bacilli and spirilla of Asiatic cholera, as far as regards their morphological characters, are identical with the bacilli and spirilla obtained by Finkler and Prior in cholera nostras; and Klebs maintains that he has seen these same forms of spirilla in the diarrhœic stools of a person suffering from pneumonia.

Why Trousseau was Miserable.—Dr. Marion Sims, in his autobiography, gives the following interesting account of Trousseau: "Trousseau was one of the greatest physicians of the age—a man endowed with physical beauty as well as fine intellect, the philosophic physician, the classical littérateur, the elegant teacher, the successful practitioner. He was without a rival. I had never known such a grand man who was purely a physician, and yet he was a very miserable man, and why? Had he not reached the highest distinction in his profession? Was he not exhibited as the highest authority in medicine all over the world? His lectures were translated into all languages, and then he was the leading practitioner, the great consultant, the fashionable doctor in Paris, and had accumulated a large fortune. Everybody spoke well of him, everybody admired him as a man; his private character was above all reproach; he had no children whom he could not recognize as his own. As the world saw the man they had the right to think and to see that he ought to be one of the happiest of men. True, he was not Court physician, but every other ambition of his life had been fully gratified, and yet he was unhappy, and why? His wife was an elegant and accomplished woman, of great beauty and fine intellect, but they were separated. He had a daughter, one of the most beautiful women in Paris, who married a man too much her senior. They were incompatible and separated. He had an only son who was a scapegrace. He was a gambler and everything else that was bad. His father was worried to death with his dissoluteness and foolish extravagance, and had to pay enormous sums of money to extricate him from his disgraceful orgies and gambling complications. He was married to a fine woman who ought to have made any man happy, but he neglected and made her miserable. . . . Trousseau had not seen his son for a long time before he died. About a fortnight or three weeks before this event, his son went to one of the gambling hells of Paris and lost all his money and more than he could pay besides. His poor father died soon after this, and his unworthy son saw a notice of his death in a London paper the next day, and I saw the tall, handsome, wretched man bending heartbroken over his good father's coffin in the Madeleine, whence he followed it to its final resting place in the Père la Chaise. We are happy or unhappy in this life as our children choose to make us."

Chloroform in the Treatment of Tape-worm a Failure.—Dr. M. B. Mattice, of Elkton, Dak., sends the following note: "Mrs. C——, thirty-five years of age, American, consulted me three months ago for tape-worm. Prescribed filix mas without success. Then prescribed ℞ chloroformi, ʒ j., simple syrup, ℥ j. M. One-third given at 7, 9, and 11 o'clock A.M., followed by ol. ricini, ʒ j., at 12 o'clock. Four hours later five feet of the worm passed. Ten days later repeated the dose and succeeded in getting but two feet more. The head still remains."

The Achievements of American Surgeons.—Ephraim McDowell, of Danville, Ky., performed ovariotomy in 1809, and the woman lived until the year 1841. Valentine Mott, in 1818, was "the first to execute the bold, brilliant, and difficult feat of taking up the innominate artery for aneurism of the subclavian." Dr. A. W. Smyth, of New Orleans, in 1864, tied simultaneously the innominate, and the common carotid arteries for subclavian aneurism, and averted death from secondary hemorrhage by ligating the vertebral artery on the fifty-fourth day. In 1833, Mott tied both carotids simultaneously, and in 1820, the first time, the common carotid for aneurism of the innominate artery. In 1845, Dr. J. Kearney Rodgers, of New York, first practised ligation of the left subclavian artery in the first portion of its course. Dr. William Gibson, of Baltimore, in 1812, first tied the common iliac artery for gun-shot wound of that vessel. For aneurism of the external iliac, Mott, in 1827, was the first to tie the common iliac artery. Dr. Robert Battey, of Rome, Ga., in 1872, successfully removed the ovaries for obstinate neuralgia. Dr. Warren Stone, of New Orleans, in 1874, cured a traumatic aneurism of the second part of the subclavian artery, by digital compression of the third division as it passes over the first rib. In 1860, Dr. E. B. Wolcott, of Milwaukee, Wis., performed extirpation of the kidney, the patient surviving the operation fifteen days, and then dying of exhaustion from profuse suppuration.

Dr. R. A. Kinloch, of Charleston, S. C., in 1863, performed enterectomy for artificial anus, according to a method urged by the late Dr. Samuel D. Gross, in 1847—namely—to excise a portion of the bowel and suture the divided ends. The prevention of hemorrhage during operations upon the extremities, by rendering them bloodless, is really an American procedure, and was practised

by the elder Pancoast and elder Gross. The employment of absorbable animal ligatures, which would not give rise to suppuration or interfere with the healing of wounds, is also of American origin. In 1814, at the suggestion of Dr. Physick, Dr. J. S. Dorsey successfully ligated a large artery in a horse with a buckskin ligature, and Dr. Joseph Hartshorne, soon afterward, at the Pennsylvania Hospital, secured the vessels, after amputation of the thigh, with strips of parchment. Concerning affections of the bones and joints, systematic manipulations in the reduction of dislocations, operations upon the nerves, the treatment of affections of the urinary and generative organs, especially the treatment of vesical calculus by rapid lithotrity, American skill, daring, and ingenuity have been displayed to the enduring credit of American surgery.—*American Supplement to Braithwaite's Retrospect.*

Patent Medicines and the Prophylaxis of Old Age.—Fourteen persons died of "old age" in Philadelphia last week, and only three of small-pox. The former appears to be the more fatal disease, but we don't hear of persons getting vaccinated in order that they may not catch it. Of the several thousand patent medicines advertised, not one is warranted to prevent a person from dying from the apparently incurable disease of "old age," and yet hundreds of these nostrums will effectually ward off the malady.—*Norristown Herald.*

Impervious Corks.—Corks may be made impervious by soaking them—best quality—for several hours in a solution of one-half ounce of glue or gelatine in a mixture of three-fourths ounce of glycerine and one pint of water, heated to a temperature of about 50° C. Such prepared corks may be rendered nearly proof against acids and other chemicals if they are dipped, after thorough drying, for ten or fifteen minutes into a melted mixture of four parts of paraffine and one part of vaseline.

Cannabis Indica as a Local Anæsthetic.—A. Aaronson writes, in the *British Journal of Dental Science*, that tincture of cannabis indica as a local anæsthetic is perfectly satisfactory. He has extracted with its aid as many as twenty-two teeth and stumps at one sitting. His plan is to dilute the tincture some three to five times, according to the probable duration of the operation. The diluted tincture is then applied in cotton-wool to cavities, if such exist, and also about the gums of the affected teeth. The beaks of the extracting forceps are also, after being warmed, dipped in the diluted tincture. In cold weather it is wise to dilute the cannabis indica.

The Practice of Medicine in Russia.—The number of medical men in Russia, according to the official statistics for 1883, is 15,231, the majority being residents of cities, and the country very badly supplied. There are medical faculties in Kief, Kazan, Charkov, Moscow, Warsaw, Helsingfors, and Dorpat, the first five of which give instruction in the Russian language, while at Helsingfors Swedish is spoken, and at Dorpat German. There is, besides, an army medical school. In the Russian schools there is a five years' graded course, with yearly examinations. At the end of this course an examination must be passed for the title of physician, after which, if it is so desired, the candidate may pass on to the doctorate examination, in order to obtain which degree a more exact knowledge of theoretical subjects is necessary than that required at the examination for the title of physician. A doctor ranks as eighth in the classes defined by the State, while a physician is one step farther down the scale. Russian medical societies are not very flourishing, owing to an every-man-for-himself spirit that exists among the physicians there. The oldest is the Society of Russian Physicians, founded in 1833. The members of this society are intensely national in their feelings, as was evidenced in one of the addresses at their semi-centennial celebration, when the speaker congratulated his hearers that at last Russian medicine had thrown off the German yoke. This feeling was also exhibited in an order recently promulgated by the Minister of War, to the effect that not more than four per cent. of the army surgeons should be Jews. There are five other societies, one of them composed chiefly of German physicians, in St. Petersburg, and seventy-three in the provinces. Considerable progress has been made in the last decade in medical journalism. The leading journal is the *Vratch*, founded by Manassein in 1880. Next to the *Vratch* comes the *Russkaya Medicina* and the *Meditsinski Vestnik*. Another journal, composed principally of abstracts, but containing also some original articles, is the *Meditsinskoye Obosrenoye*. The organ of the German physicians is the *St. Petersburger Medicinische Wochenschrift.* —*Lancet.*

Origin of Germ Theory of Disease.—A claim has been advanced in favor of Athanasius Kircher in connection with the origin of the germ theory of disease. In his work on "The Plague," published in Rome in 1658, he attributes the origin of epidemic diseases to animalculæ (germs?), and maintains that each kind of putrefaction possesses a peculiar virus which produces a definite kind of illness.

An Excuse for Delayed Calls.—This story is told as illustrating the ready wit of the late Dr. Howard, of Chelmsford. He had for a patient a very pious woman who lived in Billerica, who sent for him one day quite urgently. He did not respond so promptly as his patient desired, and when he did arrive she upbraided him sharply. "When I send for a doctor," she said, "I expect him to come right away." "But, my dear madam," he replied, "what does the Good Book say about it?" "I didn't know the Good Book referred to the subject," she testily replied. "Yes, it does," retorted the doctor, "it says the expectation of the wicked shall be cut off." The old lady was mollified.—*Lowell Courier.*

Poisoning by Aconite.—A report was lately circulated in French medical journals regarding the fatal poisoning of a person with aconite through the mistake of a druggist. Captain M. J. Farrell, of New Orleans, died the other day from a dose of aconite given through a druggist's mistake. A man in Minneapolis has escaped death from a similar cause almost by accident. A druggist there put up by mistake an ounce of tincture of aconite in a prescription brought to his store by a young man whose residence was unknown. The whole of the medicine was taken, but fortunately without evil results.

Medical Advice by Telephone.—*Husband*—My wife has a severe pain in the back of her neck, and complains of a sort of sourness in the stomach.

Physician—She has malarial colic.

Husband—What shall I do for her?

[The girl at the "central" switches off to a machinist talking to a saw-mill man.]

Machinist to Husband—I think she is covered with scales inside, about an inch thick. Let her cool down during the night, and before she fires up in the morning, take a hammer and pound her thoroughly all over, and then take a hose and hitch it to the fire-plug, and wash her out.

Husband has no further need of this doctor.—*Leonard's Med. Jour.*

The Ideal Physician.—Professor Gairdner thus describes him: 1. He must be careful and accurate, and at the same time a keen and quick observer of nature. 2. He must be able to connect his isolated observations of fact by rapid, and at the same time trustworthy, processes of reasoning. 3. He must, in dealing with emergencies, endeavor to have always presence of mind. 4. He must, as a surgeon, have much deftness of manipulation—manual dexterity, as we call it; or perhaps, still better, ambidexterity. 5. He must treasure in his memory, and be constantly increasing from day to day, large stores of various reading in his own and other languages, in order that not only past observations, but also the

vast field of scientific progress in its relation to his art, may be constantly before him, or at least freely accessible when wanted. 6. He must be able to write, at the very least in his own language, with vigor, compactness, and lucidity. 7. He must have a soul above mere money-grubbing, must on no account degrade his profession into a trade, but must be, as far as is possible to human nature, the disinterested friend, the companion—the good genius, I had almost said—of all his patients. 8. For this reason, if for no other, he must in every case have in him the distinctive essence of what is called a gentleman; and if his practice is, or is ever to be, among what are called the upper classes, he must be a gentleman, not only in principle, but in detail—not necessarily what is vulgarly and falsely often styled a fine gentleman, but a gentleman in outward manner as much as in the inner spirit. 9. He must be a man endowed with a deep sense of moral responsibility, so as to beget confidence and unfailing trust in him on the part of his fellow-men—responsibility, therefore, to them in the first instance; but underlying that, and sustaining it as surely as the root and the stem sustain the flower, a deeper and more latent responsibility to Him who is the source of all good, and therefore of all moral principle and moral responsibility whatever.

The Relation of Certain Diseases of the Eye to Gout.—Mr. Hutchinson, of London, believes that iritis, relapsing cyclitis, optic neuritis, glaucoma, and hemorrhagic retinitis may all in some cases be due to gout. He also attributes to the same cause a condition which he denominates "hot eye." He has observed this affection in those who suffer from "quiet" gout: *i.e.*, gout in which acute paroxysms never occur. Many gouty persons also suffer from ocular shooting pains, the nature of which they well understand themselves. Mr. Hutchinson also remarks that many cases of irritable hyperæsthetic and easily tired eyes in young persons are in association with inherited gout. Slight hypermetropia may be found, but glasses do no good in such cases and only increase the irritability. Referring to so-called "gouty deposits" in the eye, Mr. Hutchinson says the nearest approach to proof of gout-deposit is the occurrence of what are known as "transverse calcareous bands" in the cornea. No one has, however, yet proved that the salt deposited is that of gout. It is usually calcareous, and there is little or no evidence that urate of soda is ever deposited in the eye. In conclusion, Mr. Hutchinson disclaims a wish to see "gout in everything;" but he maintains that the gouty constitution exists, is very common in England, potent in causing disease, and remarkably hereditary.

Cocaine and its Use in America; "The Record" the First in the Field.—A London correspondent writes: Cocaine has been in use here for some little time now, and with satisfactory results, as I can testify from personal experience. Several operations—especially ophthalmic—have been performed by its aid without employing general anæsthesia. Our journals, however, are much behind The Medical Record, in which I have recently observed with interest the reports of several American experimenters with this new agent. *The Lancet* of this week contains the first communications on the subject by English observers. I note, though, that one of the articles is by an American ophthalmologist. One of our writers calls attention to the fact that Sir Robert Christison wished to call the drug cuca, and urges that cucain would be a preferable term for the alkaloid.

Gangrene from a Hypodermic Injection of Quinine.—Dr. F. Tipton, of Selma, Ala., has had a bitter experience with quinine. He had a patient suffering with a violent form of quotidian ague. Nothing would stay on the stomach, or in the rectum, so he injected into the outer aspect of the leg ten grains of quinine dissolved in water with half a grain of tartaric acid to each grain of quinine. After three days, the leg began to swell and became red; then acute spreading gangrene set in. For several days life and limb were threatened, but finally a line of demarcation appeared. The gangrenous area covered a space equal to that of both hands. Dr. Tipton writes that he had seen the injection which he used administered in about one hundred cases with no injury at all. In this case the patient showed a tendency to suppuration, even when he received slight injuries, or scratches. Our correspondent is very positive that he will not again run the risk of any such accident as the above.

Save the Fingers.—Dr. William D. Ronaldson, of Philadelphia, writing to us on the subject of conservative surgery, reports two cases which show it is often better not to yield to the impulse to cut off a bad-looking finger. A. B——, a brakeman on a railroad train, had his finger caught between the bumpers of the cars while endeavoring to couple them. The nail and flesh were torn completely off, leaving the distal extremity of the bone exposed. The injury was of such a nature that amputation of the ungual phalanx would have been permissible, but having cleansed the wound thoroughly with tepid water, a dressing of carbolized oil (1 to 15) and vaseline was applied. The finger healed in three weeks and, except for the loss of the nail, was as serviceable as before. The second case was similar to this one in treatment and results.

Hair-pin in the Uterus.—Dr. C. C. Stockard, of Columbus, Miss., writes: "In December, 1883, in the absence of her regular physician, Dr. Vaughan, I was asked to see a lady who had been told by a friend that she could introduce a hair-pin into the mouth of the womb and probably remove a clot, which was supposed to be the cause of a delay of her period. I was told that the hair-pin had slipped from the fingers and was still in the womb." Dr. Stockard introduced a probe, detected the hair-pin, and then introduced a sponge-tent. After dilatation he, with Dr. Vaughan, tried to extract the pin, but unsuccessfully. Other futile efforts were made. In a few days there was a bloody discharge, and this continued and increased till the hair-pin was removed with the forceps, fifteen days after its introduction. After the extraction the patient had no further trouble whatever.

Correcting Clinical Thermometers.—At the Yale Observatory six thousand three hundred and twenty-six physician's thermometers were corrected last year.

A Congenital Sarcomatous Caudal Growth.—Dr. W. Snowball reports in the *Australian Medical Journal* of December 15, 1884, the case of a child born with a growth attached by a pedicle to the coccyx. It was four inches long and seven in circumference. It did not communicate with the spinal canal. It was removed and found to be of a sarcomatous nature. The child died.

Priority in the Discovery and Use of the Bismuth Test for Sugar.—Dr. O. A. Fliesburg, of Stillwater, Minn., writes: "I *positively* know that this test was practised and used by Prof. A. Almén, of Upsala, Sweden, as early as 1866 or 1867, and described by him at that time, I think, in *Nordiskt Medicinskt Arkiv* or *Hygiæa*." Dr. F. himself has used this test as early as 1868, and it has been in common use in Norway, Sweden, and Denmark since that time.

Twins Born Four Days Apart.—Dr. James Douglas, of Morristown, N. J., writes: "A very unusual occurrence in the birth of twins has happened lately in my practice, one of the twins, a girl, being born at half past nine on Friday night, January 2, 1885 (breech presentation), and the other, a boy, on the following Tuesday afternoon at twenty minutes to three (head presentation), a difference of three days, seventeen hours and ten minutes. They are eight months children, the girl weighing four and one-half pounds, the boy six pounds. There was only one placenta. The mother is a healthy young woman twenty-two years of age."

ANATOMICAL GEOMETRY AND TOPONYMY:

An Introduction to the Scientific Study of Deformities.[1]

By MILTON JOSIAH ROBERTS, M.D.,

Professor of Orthopedic Surgery and Mechanical Therapeutics in the New York Post-Graduate Medical School and Hospital; Visiting Orthopedic Surgeon to the City Hospitals on Randall's Island.

Next in importance to the notation of physical facts is the determination of their quantitative relationship to other facts—their mensuration.

Geometry teaches the measurement of lines and angles. The measurement of anatomical angles, some of which are herein considered, has not only a scientific bearing upon the progress of medicine, but is of direct practical importance to every practising physician and surgeon.

Toponymy.—Desirous of accuracy and facility in our description and comparison of the attitude of individuals and the position of component parts, it is essential that we have some conventional language to represent the things and conditions dealt with. Within the limits of practical feasibility the terms used should have an intrinsic value. Words of common occurrence in medical writings, and more or less ambiguous as ordinarily used, may still be retained for the purposes of accurate description, if used with reference to some standard attitude.

Only a few toponymical terms, useful in describing deformities, are herein made mention of. The object of the present brief tentative remarks upon this subject is simply to direct attention to the importance of using such terms. The examples given are for the purpose of illustration.[2]

The surfaces or aspects of the body and their names.—As a basis for a scientific nomenclature, the body proper should be regarded as a solid having six surfaces, two ends and four sides, as shown in Fig. 1.

That end of the body which is nearer the head is called the *cephalic* end or aspect, while the opposing end of the body is termed the *caudal* aspect or end.

The surface of the body corresponding to the back is designated the *dorsal* surface or aspect, while the opposing parallel surface is termed the *ventral* aspect.

The two remaining surfaces corresponding to the right and left sides of the body, are called the *right* (*dextral*) and *left* (*sinistral*) aspects.

The surfaces or aspects of the segments of the limbs and their names.—The segments of the limbs, that is, the arms, legs, thighs, etc., like the body proper, should be regarded as six-sided solids, as indicated for the left thigh in Fig. 1.

Of the two opposing ends of any of the segments of the limbs, as, for instance, those of the thigh, that one which is attached the nearer to the body is called the *proximal* end or aspect of the segment. The opposing end of the segment is termed the *distal* aspect. In Fig. 1 the proximal end of the left thigh is indicated.

That surface of any of the segments corresponding to the extensor aspect of the limb, may be termed the *extensor* aspect of the segment, while the opposing flexor surface may be termed the *flexor* aspect of the segment. In Fig. 1 the *extensor aspect* of the left thigh is shown.

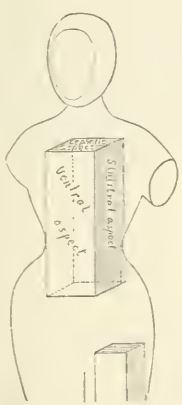

Fig. 1.

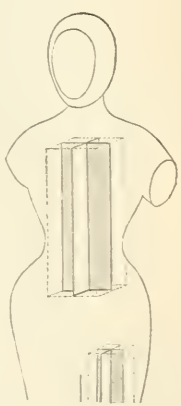

Fig. 2.

The two remaining surfaces of the segments of any of the limbs corresponding to the right and left sides of the body may be termed the *right* (*dextral*) and *left* (*sinistral*) aspects of the segment. In Fig. 1, the *sinistral* aspect of the left thigh is indicated.

The planes of the body and their names.—The planes of the body are imaginary longitudinal divisions of it into equal lateral halves, and equal dorsal and ventral halves, as indicated in Fig. 2.

That plane of the body which passes lengthwise through it from its dorsal to its ventral aspect, dividing it into two equal lateral (right and left) halves, is designated the *mesial* (*mesal*) plane of the body.

The plane which passes lengthwise through the body from the right to the left side dividing it into two equal halves (dorsal and ventral), is called the *dextro-sinistral* plane of the body (see Fig. 2).

The planes of the segments of the limbs and their names.—The planes of the segments of the limbs, as, for example, those of the thigh, are imaginary longitudinal divisions of it into equal lateral (right and left) halves, and equal flexor and extensor halves, as indicated in Fig. 2.

That plane of any of the segments of the limbs which passes lengthwise through it from its flexor to its extensor aspect, dividing it in two equal lateral (right and left) halves, is termed the *mesial* (*mesal*) plane of the segment.

The plane which passes lengthwise through any segment from its right to its left aspect dividing it into two equal (flexor and extensor) halves, is called the *right and left*, or *dextro-sinistral* plane of the segment. In Fig. 2 the dextro-sinistral and mesial planes of the left thigh are indicated.

[2] Those who are interested in the subject of anatomical terminology should not fail to consult the excellent work of Wilder & Gage on Anatomical Technology, pp. 10–45. New York, 1882. In it will be found a very complete list of terms of general applicability. Some of these have been adopted in this article. From the standpoint of the practical surgeon, however, the writer does not yet feel prepared to recommend the adoption of all the terms suggested by these authors.

The standard attitude for man.—Viewing the human subject with the object of ascertaining the position of the body and its component parts, it may be laid down as true and self-evident:

First.—That the determination of the position of the body, as a whole, depends upon a knowledge of its relationship to external surroundings.

Second.—That the determination of the position of any part of the body, with respect to other parts of the body, depends upon a knowledge of its relative relationship to those parts.

If, now, we desire to study the normal condition of the human body as to its form and symmetry, and the extent of mobility of its component parts, so as to enable us to detect and describe pathological deviations therefrom, it becomes a primary necessity to determine upon some uniform position of the body as a standard for comparison. The most commonly accepted attitude for such purposes is that which is assumed with respect to the earth's surface during locomotion. Among different vertebrates the relative position of component parts, while maintaining the attitude assumed during walking, would manifestly be subject to wide variation. In this sketch, however, we are only concerned in determining upon a standard attitude for man. This may be taken as the one assumed when standing erect, resting equal weight upon both feet, with the soft parts over the femoral condyles and malleoli in contact or equidistant from each other, the feet slightly everted, and the head, trunk, and extremities forming practically an unbroken column (see Fig. 3 [1]).

Fig. 3.

It should be borne in mind that it is possible for a given individual to maintain this standard attitude and yet not possess for each of his movable articulations the normal range of motion. Hence, the importance of knowledge regarding the extent of physiological mobility of joints.

The planes of the lower extremities.—When the individual assumes the standard attitude indicated in Figs. 3 and 4, the *mesial* plane of the lower extremity may be indicated as follows:

From a point situated at the junction of the middle with the outer third of the distance from the anterior superior spine to the symphysis, draw a line along the extensor aspect of the thigh, over the middle of the patella, to a point midway between the internal and external malleoli. In Fig. 4 the mesial plane of both lower extremities is shown.

The *dextro-sinistral* plane of the lower extremity may be indicated by drawing a line from the centre of the great trochanter midway between the flexor and extensor aspects of the limb down to a point indicating the external malleolus.

The planes of the body and those of the lower extremities not parallel.—By reference to Fig. 4 it will be seen that when the healthy individual assumes the standard attitude, the mesial planes of the lower extremities are not parallel to each other, nor to the mesial plane of the body.

The lines upon the extensor aspect of the lower extremities converge, so that were they extended they would ultimately meet and cross an extension of the line indicating the mesial plane of the body. The extent of convergence is estimated by measuring the angle formed at the junction of a line indicating the mesial plane of the leg with one parallel to the mesial plane of the body. In Fig. 4, the dotted line *r b* is parallel to the mesial plane of the body, and the angle between it and the line *r a* indicates the normal degree of longitudinal inclination toward the axis of the body (adduction) of the mesial plane of the leg. Owing to the greater proportion of breadth of pelvis in females, the degree of convergence of the lines indicating the mesial planes of the lower extremities in them is greater than in males. It is also more marked in well-developed adults than in very young females.

Not only are the distal ends of the mesial planes of the legs much nearer together than the proximal ends, but the lines upon the flexor aspect of the limbs, indicating the mesial planes, are closer together than the lines indicating these planes upon the extensor aspect of the limbs. The mesial planes of the lower limbs are thus inclined toward the mesial plane of the body in an extenso-flexor direction, *r c*, Fig. 4.

Thus it will be seen that there is not only a longitudinal convergence of the planes of the lower extremities, but there is an extenso-flexor convergence. As will appear later, these facts have an important bearing upon observations, when endeavoring to determine by instruments of precision the extent of outward or inward rotation of the limb or the extent of abduction or adduction. The normal angle of extenso-flexor convergence, or outward rotation of the thigh, is indicated by the lines *r c d*, Fig. 4, for the right limb, while the angle of normal proximo-distal convergence, or adduction of the limbs in the standard attitude, is represented by the lines *r a b*, same figure.

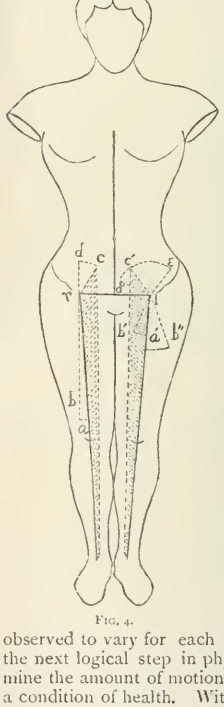

Fig. 4.

Mensuration. — Just so soon as a *qualitative* estimation of facts, physiological or pathological, is possible, the scientific physician should proceed to their *quantitative* estimation. Gold having been discovered in a given specimen of ore, the next business of the assayer is to determine its amount in coin or bullion. In a like manner, the range of normal articular mobility having been observed to vary for each individual joint of the body, the next logical step in physiological inquiry is to determine the amount of motion which each joint possesses in a condition of health. With this information at hand, we can proceed to estimate the amount of pathological deviation therefrom in any given case of disease.

In the present communication I have pointed out certain qualitative relationships which exist with regard to the planes and aspects of the body and limbs in health, and have indicated how to quantitatively define these relationships, viz., by measuring the angles which these planes make with each other, or the angle of divergence of these planes from one another. We have yet to consider some pathological deviations.

Diastrophometry.—Diastrophometry (from διαστροφή, a distortion, and μέτρον, a measure) is the word, which, with the aid of my friend, Dr. Frank P. Foster, I have determined upon to indicate the *science of measuring deformities.*

Outward rotation of the thigh and leg (Eversion).—Any increase of the angle *r c d*, Fig. 4, would necessitate the still nearer approach of the mesial lines on the

[1] Modified from the figure on the anthropometrical chart of Charles Roberts, F.R.C.S.

flexor (posterior) aspect of the limbs and a corresponding departure of the mesial lines on the extensor (anterior) aspect of the limbs, owing to the outward rotation (eversion) of the lower extremity. Such an increase, if due

Fig. 5.

Fig. 6.

Fig. 7.

to structural changes, would constitute a deformity, and the extent of deviation from the normal should be stated in the record of the case after having measured it by an instrument of precision. The angle to be measured is indicated by dotted line *l c' d'*, Fig. 4.

Inward rotation of the thigh and leg (Inversion).—Any decrease in the angle *r c d*, Fig. 4, or addition to it on the other side of the normal mesial plane, as indicated by line *l' c' e*, would constitute inversion of the limb, and the extent of deviation from the normal should be made the subject of actual mensuration as before.

Adduction of the thigh and leg.—If the angle at *r a b*, Fig. 4, is increased in consequence of structural tissue-changes, it would constitute a deformity, as indicated by line *l a' b'*, which represents the angle to be measured.

Abduction of the thigh and leg. — Any considerable decrease of the angle *r b a*, or addition to it on the other side of a line parallel with the mesial plane of the body, when the individual assumes as nearly as possible the standard attitude, indicates an abnormal condition, and the extent of the deformity should be measured. This angle is indicated by the lines *l a'' b''*, in the figure.

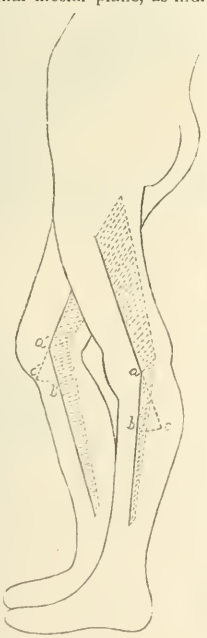

Fig. 8.

Tilting of the pelvis.—When the subject of observation standing on a level surface, endeavors to assume the standard attitude, and the anterior superior crests of the ilii are not on the same level, the condition known as tilting of the pelvis exists, and its extent should be accordingly determined. The lines *m l e*, Fig. 5, indicate the angle to be measured under such circumstances. In the same figure adduction of the right leg, *r b a*, and abduction of the left limb, *l b' a'*, are indicated. The dotted lines *r a* and *l a'* represent the normal direction of the mesial planes of the lower extremities. The determination of the pelvic tilt and of the existence of pathological abduction and adduction, are of diagnostic value in many examples of orthopedic maladies. The importance of knowledge regarding these points has been made the subject of an interesting paper by Dr. William S. Halsted.[1]

Flexion and extension of the thigh.—The surface lines indicating the right and left (dextro-sinistral) planes of the body and thigh, Fig. 6, are continuous. Any deviation of the femoral line in a flexo-extensor direction, as indicated by the arrow in the figure, when the individual is trying to assume the standard attitude, indicates an abnormality of flexion. The angle to be measured is indicated by the lines *r a b*, Fig. 6. The error is often made of regarding the angle *r b d* as that indicating the degree of flexion.[2] The lines *r c a*, indicate the angle to be measured in extension of the thigh.

Flexion of the knee.—In health, with the leg straight, the mesial and dextro-sinistral planes of the lower extremity cross each other at right angles and are continuous throughout the entire length of the limb, as represented in the right extremity, Fig. 7. If, however, the knee is flexed, the planes of the thigh and leg are no longer continuous, and the degree of flexion is to be determined by measuring the angle formed by the junction of the dextro-sinistral plane of the thigh with that of the leg, *a b c*, Fig. 7.

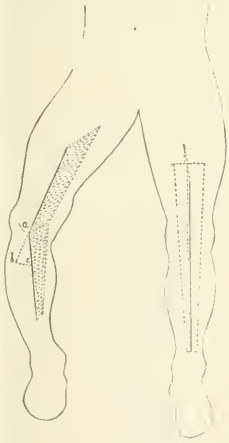

Fig. 9.

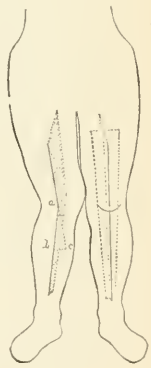

Fig. 10.

Hyperextension of the knee.—In hyperextension of the knee, Fig. 8, *a b c*, the angle to be measured, is upon the flexor aspect of the dextro-sinistral plane instead of being upon the extensor aspect, as in flexion *a' b' c'*.

Abduction of the knee.—In out-knee, or abduction of the knee, the mesial planes of the thigh and leg are inclined away from the axis of the body. The angle to be measured lies upon the external aspect of these planes, and is indicated in Fig. 9 by the letters *a b c*.

Adduction of the knee.—Fig. 10 illustrates the condition known as in-knee. In this deformity the mesial planes are inclined toward the axis of the body, and the angle to be measured, *a b c*, lies upon the internal or adductor aspect of these planes.

Adduction of the knee with hyperextension.—When in-knee deformity is complicated by hyperextension of the joint, as is not infrequently the case, the angles formed at the junction of the mesial and dextro-sinistral planes of the thigh, with the corresponding planes of the leg,

[1] The Effects of Adduction and Abduction on the Length of the Limb in Fractures of the Neck of the Femur. New York Medical Journal, March 22, 1884.

[2] *Vide* The Hip and its Diseases, by V. P. Gibney, A.M., M.D., p. 29.

must be determined in order to correctly state the extent of the deformity. The angles to be measured are indicated by the lines *a b c*, and *a' c b'*, Fig. 11.

FIG. 11.

FIG. 12.

Adduction of the knee with flexion.—When the deformity is one of in-knee with flexion, the angles to be measured are those indicated in Fig. 12 by the lines *a b c* and *a' c b'*.

Adduction and flexion of the knee with outward rotation of the leg.—When the complicated condition of in-knee, flexion, and outward rotation of the leg exists, it becomes necessary to measure the three angles indicated in Fig. 13 by the lines *a b c*, *a' c b'*, and *d e f*.

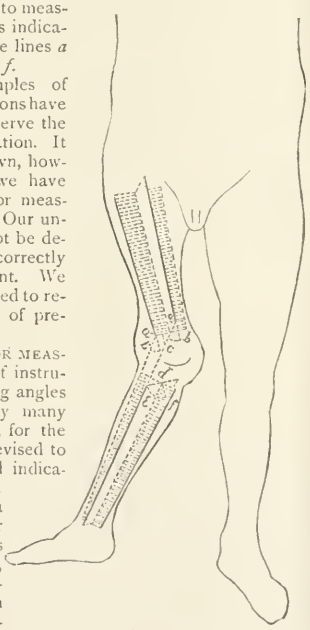

FIG. 13.

Sufficient examples of pathological deviations have now been cited to serve the purposes of illustration. It remains to be shown, however, what means we have at our command for measuring these angles. Our unaided senses cannot be depended upon to correctly estimate their extent. We are, therefore, obliged to resort to instruments of precision.

INSTRUMENTS FOR MEASURING ANGLES.—Of instruments for measuring angles there exist already many forms. They have, for the most part, been devised to meet other special indications than are herein mentioned, and, as a natural result, their range of usefulness is limited. When, therefore, we attempt to use them for the purposes indicated in this paper, we find them ill adapted or absolutely useless for making the desired observations. Hence it became necessary to invent new instruments for the specific purpose of more accurately and conveniently measuring the angles under consideration. To this work I have, during the past six years, given much time and careful consideration. Space will not here permit of entering into details. Out of a number of mathematical instruments which I have invented or modified for this purpose, I shall now describe only three.

The articular goniometer.—The articular goniometer, Fig. 14, was the outgrowth of my earlier endeavors to devise an instrument having a wider range of usefulness in the measurement of joint angles than those in common use. It has been in actual use in my hands about five

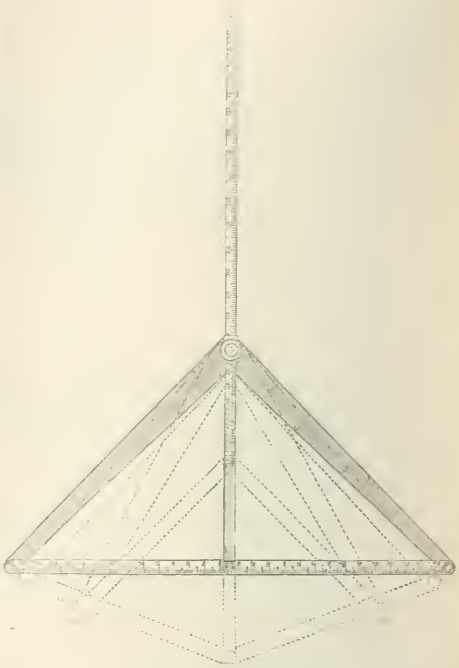

FIG. 14.

years. It is so constructed as to measure the mutual inclination of the mesial or dextro-sinistral planes of two adjacent segments of the limbs or body, or the inclina-

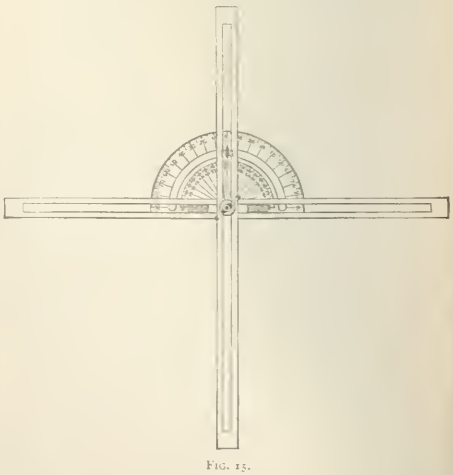

FIG. 15.

tion of the flexor or extensor aspects of the same, no matter how great the deviation from the normal may be, providing the deviation is confined to one plane. The

graduations on the arms of the instrument and its working are so well shown in the figure as to require no detailed explanation.

The adjustable protractor.—The instrument illustrated in Fig. 15 is a modification of one form of protractor already in use. Both arms are made adjustable. There are two sets of graduations and three series of figures marked on the face of the semicircle. With this instrument the tilt of the pelvis, the adduction or abduction of any member, whether upon the right or left side of the body, or the flexion or extension of one segment upon another, can be speedily and accurately determined providing the observation be limited to one plane.

It is the only protractor which I have met with, the arms of which can be made sufficiently short to record the angle of deformity in examples of spinal caries.

The epipedometer.—Fig. 16 represents an instrument which I have invented for simultaneously recording any combination of angular junctures of the planes of appendicular segments which can be found in the human body in health or disease.

The planes of the instrument, crossing each other at right angles correspond to the imaginary planes (*mesial* and *dextro-sinistral*) of the body and limbs already described. By means of the three graduated dials with which it is provided, the exact extent and direction of any deviation from the normal can be measured in degrees with the greatest facility.

A section of the instrument, amounting to one-half the length of the lower planes

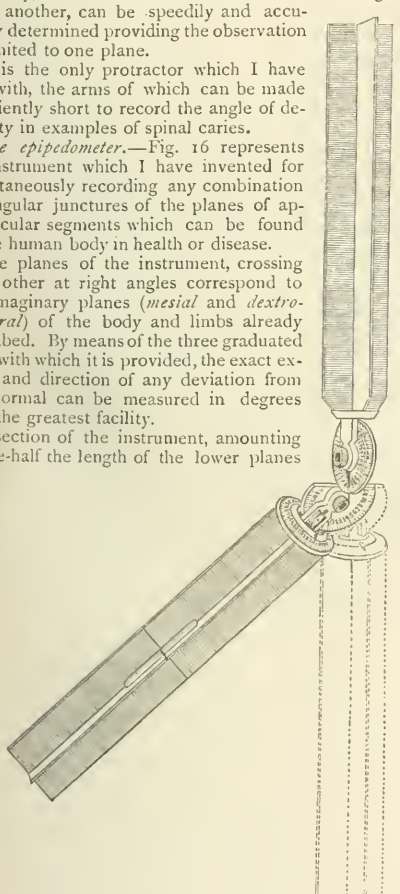

Fig. 16.

as indicated in the figure by a dark, transverse line, is made removable in order to render it more convenient of use in measuring the extent of deformity in cases of club-foot.

As this instrument measures the angle of juncture of the planes of the body and limbs, I have named it the *epipedometer* (from ἐπίπεδον, a plane, and μέτρον, a measure).

With the above instruments, and the requisite skill in their use, the orthopedic surgeon will find himself as thoroughly equipped for the accurate measurement of angular deformities of the body as the oculist is with his ophthalmoscope and set of trial glasses for the measurement of errors of refraction.

PNEUMONIA IN YOUNG CHILDREN.[1]

By L. EMMETT HOLT, A.M., M.D.,

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE NORTHWESTERN DISPENSARY, INSTRUCTOR IN THE NEW YORK POLYCLINIC.

(Concluded from page 178.)

How does broncho-pneumonia terminate?—Of the fatal cases the vast majority die during the acute stage. Of those who survive this period by far the greater number resolve in from three to four weeks. Resolution is more rapid in those cases of disseminated pneumonia than where consolidated areas of considerable extent have formed. In these it is necessarily much slower than in lobar pneumonia, where the inflammatory products are wholly or chiefly within the alveoli and the bronchi.

The most interesting question is: What becomes of those cases (by no means few in number) which at the end of six weeks or two months have shown little or no tendency to resolve, the physical signs remaining as they were during the height of the disease? Three answers may be given:

1. They may become tubercular.
2. They may terminate in chronic fibroid induration.
3. They may recover perfectly.

First, then, in regard to *tuberculosis*. Is it common for a simple broncho-pneumonia to result in cheesy degeneration of the inflammatory products and the patient die of tuberculosis? I have not yet met with a single case which from the clinical history would justify such a diagnosis. Rilliet and Barthez, who are the authors of probably the best article upon the pneumonia of children in any language, state, in their last edition, that this never occurs. That if cheesy degeneration exist, the process must have been tubercular from the outset. Most authorities are not willing at present to go quite so far as this, but admit its possibility where the patient has a strong predisposition to tuberculosis.

We may, I think, safely take the ground that a case of unresolved broncho-pneumonia is extremely unlikely to develop tuberculosis, if there has been beforehand no sufficient grounds for believing the patient to be tubercular.

Secondly, fibroid induration.—Reverting to the pathology of the disease we find that there is in all cases more or less involvement of the fibrous walls of the bronchi, and the interstitial tissue of the lung. The greater the duration of the disease the more marked these changes are. The acute process may pass into a chronic one, with the production of new connective tissue. This may go on until a whole lobe or even a whole lung is converted into almost a solid mass of fibrous tissue, with obliteration of the air-cells, more or less complete dilatation of the bronchi, and thickening of the pleura. Such a lung is, of course, hopelessly crippled. This condition is generally the result of repeated attacks of acute inflammation, or of exacerbations of a chronic process. These patients suffer more or less from pulmonary symptoms, and frequently die in some of these exacerbations, or they may live on indefinitely.

Thirdly, complete recovery.—I know it is necessary nowadays, in speaking of recovery, to define exactly what is meant by it. I use the word in a clinical sense, not in an anatomical one. By recovery in the class of cases we are considering, I understand a condition in which the lung performs its functions normally, so far as we can judge from the patient's symptoms, and when the ordinary methods of physical examination fail to detect any material alteration of the signs present in health.

That it is possible for a lung in which consolidation from broncho-pneumonia has existed for several months to return to a condition in which no changes would be apparent under the microscope, I doubt very much. Using the term in the sense defined, I believe that the greater number of these cases ultimately recover perfectly. All

[1] Read before the Section of Obstetrics and Diseases of Children, New York Academy of Medicine, January 22, 1885.

branches of pathology illustrate the wonderful reparative powers of nature in young children. This is strikingly shown in diseases of bone. The lungs form no exception to this rule. Lung consolidations, which in adults would seem hopeless, are disposed of in the most surprising manner by nature in young children. I have followed many of these cases for two years and more, and have been astonished beyond measure in some of them to find how completely the disease had cleared up, sometimes under circumstances, too, anything but favorable. I have come to expect this result when the patient has not a strong tubercular predisposition, or when the surroundings were not hopelessly bad.

There are some special conditions which may always be expected to delay resolution. This is particularly true of whooping-cough. It seems well-nigh impossible for the lungs to clear up while whooping-cough continues.

Yet I have learned never to despair of these cases. The dangers are very great during the acute stage of the pneumonia, half of my cases died. If, however, the child does withstand the dangers of this period, I expect him to recover, except under the conditions just stated, although resolution may be delayed for many months. I cannot forbear mentioning a few cases under this head.

A boy, aged two and one-half years, came under observation in July, 1882, with whooping-cough. He developed an acute broncho-pneumonia, in the left lung chiefly. The lower lobe posteriorly became almost completely consolidated, and there were small patches of consolidation above. Then the right lung became involved, and the middle and lower lobes behind almost solid. After three or four weeks his fever gradually subsided, but his whooping-cough continued, and the lungs showed no disposition to clear up. He became much wasted, exceedingly anæmic, and the case seemed hopeless. Another physician, a well-recognized authority, saw the case with me. He concurred in the opinion I had already formed that the process in the lungs was tubercular, and the prognosis absolutely bad. The case passed from under my care, but I had an opportunity to examine the patient six months later. I found that the right lung had almost entirely resolved, while as yet but little change had taken place in the left.

One year from his attack I saw him again, there was good respiratory murmur over both lungs, a little higher pitched on the left side than the right, with slight dulness here, a few fine râles, and some old pleuritic friction. His general condition was excellent, he had grown plump and hearty. I have examined him at intervals of a few months since that time, and have noted a gradual disappearance of the abnormal signs. I saw him this present month, two and one-half years after his attack, and on a very thorough examination the only thing I could detect was an occasional coarse râle over the left base. There was no retraction of the chest, no dulness, the respiratory and voice sounds were normal. Nothing, in fact, existed to lead one to suppose that the lungs had ever been the seat of serious disease.

Another case, fifteen months old, had first whooping-cough, then acute broncho-pneumonia; after this had existed a week he came down with measles, which was farther complicated by thrush and a very obstinate diarrhœa. An extension of the pneumonia took place with the measles. There was consolidation at the left apex and in the right middle lobe behind and in the axillary region, with pretty generally diffused pneumonia along the posterior borders of both lungs. Despite all these complications, and extremely unfavorable hygienic surroundings, he disappointed us all by surviving. His fever, which was high at the outset, gradually wore away, and after a couple of months subsided altogether, and his lungs began slowly to clear up, and he made a good recovery. He was seen eighteen months afterward, and had grown to a stout, healthy boy, showing no signs of his previous disease.

But one more case: A boy, aged three years, came under my care in September, 1884, with whooping-cough which had already lasted six weeks, and for two weeks had been very severe. He developed acute broncho-pneumonia, involving the base of the left lung behind. As the acute febrile symptoms were subsiding an exacerbation took place, and a large part of the middle and lower lobes of the right side were invaded, with an extension of the disease in the left lung. The temperature had fallen nearly to the normal again, and the case began to look a little more promising, when I was called, October 28th, to find him with a temperature of 103°. The next day it rose to 105°, and a profuse eruption came out over the body, which a typical desquamation, beginning ten days later, proved to be scarlet fever. This was borne quite as well as could have been expected, and brought no new complication except that the consolidation in the lungs became a little more extensive and more complete. During desquamation a crop of furuncles appeared over the trunk, face, and extremities. This was only a side issue, and was disposed of in a few days. I should not omit to state that during all this time his whooping-cough continued. By means of chloral and belladonna it was much modified, but the minimum reached was eight or ten severe paroxysms a day. After the furunculosis he began slowly to gain in flesh, had very little fever, and in a few weeks was able to get about.

I examined him on December 19th, and found signs of complete consolidation over the whole of the left lower lobe, and almost complete over the greater part of the middle and lower lobes of the right side posteriorly. These signs were almost identical with those recorded early in October. His whooping-cough, however, had almost subsided.

At the next examination, made two weeks later, I was astonished to find that the right lung had almost entirely resolved. Upon the left side the dulness was very slight. The breathing over the lower lobe was broncho-vesicular, with moist râles, while before it had been pure bronchial with no râles, and the dulness had been complete. He is still under treatment, but in excellent condition, and bids fair to make as good a recovery as the first case related.[1]

The mortality in acute broncho-pneumonia is very high under all circumstances, and contrasts strongly with lobar pneumonia in children. The death-rate in my cases was forty per cent.; of the cases in which the disease was secondary, forty-six per cent.; of those presumably primary, twenty-nine per cent. died. These figures accord pretty well with those given by others. All agree that the prognosis is worst where the pneumonia complicates whooping-cough. Ziemssen gives the mortality of these cases as fifty per cent. Occurring with measles it depends much upon the character of the epidemic. Ziemssen gives thirty-three per cent. as the average death-rate. The younger the child, other things being equal, the worse the prognosis. It is also worse where any constitutional taint exists, such as syphilis, scrofula, or tuberculosis. Rickets introduces two elements of danger—the interference with respiration from mechanical causes depending upon deformity of the chest, and the enfeebled, flabby condition of the muscles, which are almost as characteristic of this disease as is the bone softening.

Of the special symptoms which indicate an unfavorable termination, should be mentioned a persistent high temperature, a pulse not only rapid but small and thready, cessation of the cough, convulsions late in the disease, an abundant diarrhœa, drying up of the secretions of the mouth, nose, or eyes, steady emaciation, great irritability, or the reverse, marked drowsiness, and slight cyanosis; but more than any other single symptom, the character of the respiration. Of sixteen cases in which the number of respirations reached eighty a minute, eleven proved fatal; of six cases in which it

[1] An examination February 16th, showed almost complete disappearance of all these signs.

was ninety or over, all died. Yet it is not always the rapidity of the respirations which is our best guide. Although not rapid, they may be feeble, jerking, superficial, or irregular, all of these characteristics being unfavorable.

Diagnosis.—Is it possible to make a diagnosis between lobar and broncho-pneumonia, and, if possible, is this of any practical value? I answer both these questions in the affirmative. In the matter of prognosis it is of very great importance, as the figures above cited show. In the vast majority of cases, the two diseases can be distinguished by the symptoms and physical signs.

The following are some of the most striking points of contrast. Under one year old, the chances are greatly in favor of broncho-pneumonia. Lobar, like the disease in adults, is much more prevalent in the spring months, while broncho-pneumonia, in so far as it is influenced by season at all, is quite as common late in fall and winter as in the spring.

Lobar pneumonia is usually primary, occurs most often in stout, robust children, and the onset is sudden and violent. Broncho-pneumonia is usually secondary, follows all debilitating influences, and is more often developed gradually or insidiously. Lobar pneumonia is usually limited to one lobe, often only a portion of a lobe, the area is sharply defined, the rest of this lung and the opposite lung being usually free. Broncho-pneumonia almost invariably affects both sides, and may be diffused through nearly the whole of both lungs; when consolidated areas exist they shade off gradually into the surrounding parts, and are irregularly scattered through the lung.

Râles in lobar pneumonia belong to the early stage, and then usually disappear till resolution commences; consolidation comes early. In broncho-pneumonia the signs of consolidation are always preceded for some days by those of capillary bronchitis. Consolidation comes later, or may not come at all. When present its signs are almost never pure, but bronchial signs are mingled with them, heard at its margins, and in the other lung. The persistence of the subcrepitant râle throughout the disease is almost of itself conclusive proof of broncho-pneumonia. If the pneumonia is primary and at the apex only, it can be pronounced lobar without hesitation.

In doubtful cases the mode of termination generally settles the question, being critical in lobar, gradual in broncho-pneumonia.

The diagnosis between broncho-pneumonia and tuberculosis is always a matter of great difficulty and attended with more or less uncertainty. The persistence of an afternoon fever, the more rapid progress of the disease, the greater emaciation, and a distinct tubercular family history—all point to this latter disease in the lungs. Symptoms of tubercular disease in the glands, bones, intestines, or brain, coexisting, increase this probability. In a large number of cases the question can only be decided in the dead-house.

Treatment.—I have not much faith in drugs in the management of pneumonia in children. I have tried most of those usually recommended very extensively, and am able to speak quite positively of what they do *not* do. Quinine and the other cinchona alkaloids, I believe, have little effect in aborting the disease, shortening its course, or in reducing the temperature. I have tried them in early and late stages, in small and in large doses, and, except in those cases in which there was an undoubted malarial complication, I have found them totally without benefit. Very large doses, such as twenty or thirty grains of quinine to a young child, I believe to be positively injurious, if not dangerous. It frequently upsets the stomach, is always difficult to administer, and renders more difficult the administration of necessary nourishment and stimulants. I feel sure that my cases have done better since I left off its use altogether, except as when indicated above.

Aconite in the very beginning of lobar pneumonia I have used considerably in very small frequent doses. Patients are usually rendered more comfortable by its use, and it adds no disturbing element; but that it essentially modifies the intensity or the duration of the disease I am very doubtful. I have seen enough benefit from it to encourage me to continue in its use.

The use of emetics in broncho-pneumonia when the dyspnœa is very great, the face slightly cyanotic, the extremities cold, and the tubes filled with mucus, as shown by large and small moist râles over the whole chest, I have tried in a number of cases. I cannot now remember a single instance in which any decided benefit followed; in several I am sure it hastened death. Ipecac was the emetic used. With local revulsive measures, which I will presently describe, and the free use of stimulants, I have been much more successful.

The treatment I have finally settled upon can be briefly summarized in a few words: *nourishment, opium, alcohol, local applications.*

If the child be at the breast it should be kept there, care being taken that it be not nursed too frequently. Of this there is danger from the great thirst which accompanies the fever; this may be allayed by water in which the stimulants are given. In older children a milk diet, as in other acute diseases.

Opium I believe to be worth more in acute pneumonia than all other drugs combined. It quiets the restlessness, relieves the pain and the cough, and, perhaps more important than all, sustains the nervous system under the strain which the disease produces, and in this way seems to exercise a beneficial effect upon the inflammatory process. I have found the tablet triturates of morphia, $\frac{1}{30}$ grain, a very eligible preparation; one may be given every two or three hours to a child a year old. Of late I have used a great deal, and have come to prefer the tincture of opium and ipecac, or the liquid Dover's powder to any other preparation of opium; it may be given in drop doses at the same intervals.

Alcoholic stimulants in a large number of cases of lobar pneumonia are never needed. In broncho-pneumonia they are often required from the outset. They should be given fearlessly, but of course intelligently. I have never regretted giving too much, but have often regretted beginning the larger doses too late. It is a mistake to suppose that children do not bear alcoholic stimulants well. The quantity must be regulated by the character of the pulse, the breathing, but most of all by the general aspect of the patient. From one to two ounces of brandy in twenty-four hours is the quantity I have generally given to a child a year old; double the amount for one two to three years old. In very bad cases it may be necessary to go much beyond these quantities, up to six ounces a day, or even more.

Local applications.—For the average case the following will be found to serve a very good purpose: next to the skin is placed a layer of cotton wadding an inch thick, enveloping the whole chest; over this is placed a tightly-fitting oiled-silk shirt, to which the cotton is sewed to prevent its slipping. This protects the chest against any atmospheric changes, and keeps it at a uniform temperature. When once applied it need not be changed for a week; the patient is not disturbed by the necessity of frequent renewal. Poultices, unless very carefully, intelligently, and conscientiously applied, are capable of doing quite as much harm as good. Cold poultices, poultices that have slipped from their places and lain for hours, perhaps, over the loins or over the epigastrium, who has not seen them? The exposure and disturbance of the patient which the frequent renewal of a poultice requires are decided objections. Yet, after all has been said, they are still, I firmly believe, when properly used, the most efficient means we possess in the severe cases, especially where the disease is diffuse or generalized. Their efficiency is much increased by the addition of mustard. In the condition above described, in speaking of emetics, where both lungs are in a state of intense engorgement and the heart is failing, much better results than by emetics

may be obtained by putting the child in a mustard bath up to its hips until the skin is reddened thoroughly, the application of a mustard poultice large enough to envelop the whole chest, and the internal administration of brandy in teaspoonful doses every twenty or thirty minutes. I have had the satisfaction of seeing several very bad cases saved, I think, by this treatment. One, a little girl of eight months, in which the temperature was 106.4°, the respiration 80, and the pulse 200.

Bearing in mind the fact that in broncho-pneumonia it is the respiratory function which first fails—this being followed by collapse and congestion—we should use every means in our power to sustain respiration and to remove every possible source of embarrassment. Friction of the chest, daily, with some mild counter-irritant, may be used in conjunction with the oil-silk and cotton. Every means possible should be employed to keep up a good peripheral circulation and to prevent congestion of the unaffected lung, which is so often the immediate cause of death. The child should not be allowed to lie too long in one position.

Carbonate of ammonia is very often of decided benefit both as a respiratory and a heart stimulant. It is best given frequently and in small doses. The use of oxygen inhalations I have never had an opportunity of trying when they seemed indicated. Many are loud in their praise, and it seems as though we might expect much from their use.

In one case of lobar pneumonia strikingly beneficial results were obtained from the use of the cold pack. The patient was a stout boy of two years, and the only part of the lung affected was the extreme right apex. After being above 105° for five days the temperature rose on the eighth day of the disease to 106¾°. The patient lay quietly, but was not stupid, with very great prostration. The pulse was 180 and weak. He was put first in a mustard bath for fifteen minutes without any apparent effect and then in a cold pack which was kept up eight hours. The temperature gradually came down to 103½° and did not again go above that point, though the crisis did not occur for three days.

In broncho-pneumonia, where the temperature was very high, other conditions have always been present, like intense pulmonary congestion and cyanosis, which made me afraid to use cold applications in any form.

To promote resolution in broncho-pneumonia in addition to the usual internal remedies employed, cod-liver oil, iron, etc., I have been in the habit of keeping up a mild counter-irritation over the chest by iodine or friction with some stimulating liniment.

23 Park Avenue.

Calomel in Acute Lobar Pneumonia.—Dr. H. B. Robinson, of Blount Springs, Ala., states that in the past thirty years he has treated pneumonia with mercury, opium, ipecac, quinine, blistering, and occasionally bleeding. He has lost but four cases during his practice. A strong young negro, suffering from the disease, grew progressively worse, and Dr. R. had about given him up when he concluded to dress a blister which he had drawn on his back with mercurial ointment. He did so, and next morning, to his surprise, the patient was much better, and finally recovered. A child, five years of age, nearly moribund with pneumonia (lobular?), had a blister drawn on the back. This was dressed with bismuth subnitrate, and next day the child began to recover. These cases simply show that even bad cases of pneumonia may suddenly take a favorable turn. It is a serious question if the treatment had anything to do with the favorable change in the case.

Dilute Phosphoric Acid is a pleasant acid in fevers, nd dissolves phosphates in the urine quite as well as the other mineral acids. It is well given in lemonade or syrup of raspberries.

WHAT WE KNOW ABOUT THE BACTERIAL ORIGIN AND TREATMENT OF ASIATIC CHOLERA.

By JOHN C. PETERS, M.D.,[1]

NEW YORK.

In 1854 Dr. Dundas Thomson found many vibrios in the atmosphere of wards filled with cholera patients, fewer in wards half filled, and very few in empty wards. They were also abundant in the air of sewers which was *alkaline*. I may add here that malarious soils are also *alkaline*. He also found vibriones in great abundance in the rice-water discharges, in the drinking-water of affected places, and even in the blood of some cholera patients. Although found in other disorders, these vibrios were vastly more abundant in cholera.

These probably were merely the bacteria of common putrefaction, with specfic ones, if there are any, concealed by the massive accumulations of the others, or not detectable by the microscopes or methods of those early times.

In the same year Dr. Hassall noted three conditions or circumstances which he supposed to be necessary for the development of vibriones: First, an alkaline fluid; second, organic matter in a state of decomposition; and third, a certain degree of warmth. Summed up this is heat, moisture, filth, or something in a state of decomposition, perhaps putrefaction, and germs.

He thought that these germs, when introduced into the alimentary canals of cholera patients, were brought into conditions highly favorable to their development. Their multiplication took place with almost inconceivable rapidity in twenty-five cases, seemingly because the rice-water discharges are *always* alkaline, offensive, and the bowels warm. He thought the fluids thrown out into the bowels were more than usually prone to decomposition and more than commonly *alkaline*. He even went so far as to suggest that these facts would account for the success of sulphuric acid in the treatment of cholera, which was then coming in great vogue. He regarded it as an antiseptic acid, which prevented decomposition and putrefaction, and also neutralized alkalies, while it was decidedly a refreshing and cooling remedy.

Hassall also found vibrios in the urine and upon the soiled clothes of cholera subjects, where they not only abounded, but were alive and very active. He did not suggest the disinfection of these clothes with dilute acids, like acetic or phosphoric, but I will do it for him. He thought these germs were common, not comma, germs, and killed merely from their numbers.

In 1872 Dr. Nedwetsky found bacteria, which he did not distinguish from common bacteria, in large quantities in rice-water discharges, and set about to kill them all in a rudely scientific, but exceedingly practical way. He always used two drachms of rice-water discharge in all his experiments, and found that one drachm of laudanum did not kill the bacteria in this small quantity; nor one drachm of tincture of nux vomica; neither did alcohol kill them; nor ten grains of quinine; nor thirty grammes of camphor; nor five or even ten drops of strong so-called carbolic acid, which is not an acid, but an alcohol; nor one drachm of tar; nor ten grains of calomel, between the particles of which the bacteria not only lived and moved, but on the fifth and sixth days new granular masses and new crops of bacteria had formed. The same had happened with camphor. One drachm of a strong solution of chloral did not kill bacteria, and it required one drachm of chloroform, and a saturated solution of sulphate of iron.

If there is any truth in science or sound reasoning, all these favorite remedies may be useful in other diarrhœas and in cholera morbus, but cannot be reliable in true specific choleraic diarrhœa, and we know they all fail in fully developed cholera. Physicians see very few cases of true cholera among the better classes, and every one supposes in cholera times that the least diarrhœa is chol-

eraic. Hence, perhaps the great reputation of these remedies. Unless a patient has been exposed to the poison of cholera, his or her diarrhœa is of no more importance, except for the anxiety, than at any other time; unless we admit that the poison rises into the air.

But Nedwetsky found that ten grammes of tannin killed bacteria, also weak chlorine water and dilute sulphuric, muriatic, and nitric acids. Scientifically these are the most reliable remedies, and all have been found useful. The use of dilute acids, especially acetic, lactic, and phosphoric, may prevent cholera by keeping the stomach acid, as it is always alkaline except when digestion is going on. Pepsine with the addition of acid eats up bacteria. Table-salt and vinegar are good germicides; the former is decomposed in the stomach and its muriatic acid goes to reinforce the acid gastric juice, of which lactic acid is also a constituent. Lemon-juice and vinegar are allowable and useful, but both contain potash; the former is a citrate of potash, the latter an acetate; still they are decomposed in the stomach and the acids liberated. If the stomach be kept reasonably acid by pure acids, not by the impure butyric, acetic, and others which prevail in indigestion, all bacteria will be killed before they reach the bowels, which are always alkaline in health.

Still clinical experience rules higher than pure, perhaps imperfect, science. The believers in camphor, calomel, and opium should only be less positive, or perhaps lessen the size of their doses when they have diarrhœa and combined fright and anxiety, not cholera to deal with. I will be loth to give up opium, and perhaps an occasional dose of calomel, but I certainly will give dilute acids also.

Next as to the quantities. To put a few drops or grammes of any medicine into stomach and bowels containing quarts, perhaps gallons of diarrhœal fluids seems folly. The thirst is great in cholera, and perhaps pints and quarts of very dilute acids may be given as common drinks. If the stomach is not yet affected, perhaps the absorption of small doses may take place. Tannin, calomel, and bismuth have the advantage that they can cling to and plaster themselves on the walls of the bowels and not be swept away as small quantities of liquids will be.

POLIOMYELITIS ANTERIOR IN THE ADULT.

By A. D. ROCKWELL, A.M., M.D.,
NEW YORK.

Since Dr. Seguin, in 1874, called renewed attention to that grave but somewhat rare disease, poliomyelitis anterior in the adult,[1] the subject has been somewhat better understood. Indeed, no one who has carefully studied the admirable analysis therein given of this disease need remain in doubt as to its distinctive character, nor hesitate long in the diagnosis. In the intervening time, however, comparatively little has been written about it, and I was therefore glad to see in a late number of the *American Journal of the Medical Sciences*, and in The Medical Record of February 7th, two independent reports of cases, accompanied by an intelligent discussion of the subject in all its phases, and especially in regard to differentiation. It would seem that no one ought to confound subacute or chronic atrophic paralysis in the adult with locomotor ataxia, and yet within a year I have met with two cases where the mistake was committed. Posterior spinal sclerosis has been so freely discussed of late years that it has become one of the familiar things in medicine, and the tendency among those who give little thought to the more obscure diseases of the central nervous system is to confound it with forms of paralysis having an entirely different origin. One of the two cases to which reference is made I should therefore like briefly to report, for the two-fold purpose of still further emphasizing the subject in regard to its differentiation, and to illustrate the very marked and rapid results of proper methods of treatment. The case is in itself, moreover, well worthy of record, from the fact that it was one of those rare illustrations where general paralysis of the most extensive and profound character prevailed; Duchenne, as remarked by Dr. McIntosh in his article, having met but five such cases out of a total of sixty-two observed.

Case.—Mr. F——, aged about thirty years, first observed in November, 1882, a momentary hesitancy in attempts to move, especially in going up stairs, and soon after was compelled to take to his bed because of what he termed "exhaustion." Improved somewhat, and in January, 1883, went to Europe. Returned the following March feeling generally much better, but still weak, and with the same undefinable sense of hesitancy in the limbs. This symptom gradually left him and he was fairly well during the summer, but after a while he again experienced the sudden "catch," as he termed it, when about to ascend the stairs. On one occasion, in August, when feeling quite well, he went into the surf and stayed an unusually long time. On coming out he felt giddy, stiff, and tired, and was never as well afterward.

One day in September, after a walk, he began to feel "very bad," and took immediately to his bed, from which he was unable to rise for many months. In a week's time he was completely paralyzed in every limb; he could with difficulty move even his head, and in addition he became afflicted with diplopia and an entire loss of voice.

He remained in this condition with no improvement excepting as to his voice and eyes, until I saw him January 10, 1884. At that time he could speak only in a whisper, and the eyes were yet somewhat affected. The paralysis was so complete that it was impossible to move even a finger or toe, and the electro-muscular contractility was lost equally to both the galvanic and faradic currents. This is a point to be especially noted, for in these cases it is seldom, according to my experience, that galvano-muscular contractility is entirely lost, although the reactions that do occur are likely to be the reactions of degeneration; and in this case, when some response to galvanism was finally observed, qualitative as well as quantitative changes were readily noticed, the anodal closing contraction being stronger than the cathodal closing contraction. In locomotor ataxia as is well known, there is little if any change in the electrical reaction.

All of the paralyzed muscles were atrophied to the last degree, but there was a notable absence of any tendency to bed-sores, spinal epilepsy, permanent anæsthesia, or paralysis of the bladder or sphincter ani. A word in regard to the treatment of poliomyelitis anterior as illustrated more especially by the case under consideration. Dr. Gustavus Eliot, in his very valuable article on this disease,[1] and in his enumeration of the various plans of treatment, remarks that massage and electricity should be used as soon as there is any evidence of improvement. If by this he means that counter-irritation and ergot, which come first in the list, should be used until there are evidences of returning power of motion, I should very strongly dissent. Just so soon as the acute symptoms pass away, and immediately in the subacute and chronic forms, it is proper to begin the application of galvanism. In less than two months under almost daily applications of galvanism, the patient in the case under consideration improved in the most marked degree. Electro-muscular contractility returned, the limbs greatly developed, while a very decided degree of power prevailed in all the extremities, the patient being able to throw his arms and legs in any direction.

When it is remembered that the paralysis had been profound and without the slightest evidence of improvement for three months, excepting as to the eyes and voice, the very positive and immediate effects of treatment will be better appreciated.

INTUBATION OF THE LARYNX.

By E. F. BRUSH, M.D.,

PRESIDENT OF THE WESTCHESTER COUNTY MEDICAL SOCIETY, NEW YORK.

On the morning of January 5, 1885, I saw in one of the wards of the New York Foundling Asylum, a boy three and a half years of age, just recovered from measles, suffering from pneumonia and commencing inflammatory croup. I saw him again the following day. His breathing was labored, countenance distressed, and there was great restlessness. I saw him for the third time on the morning of the seventh; the face was pale, the eyelids were half-closed showing the whites of the eyes, the head was thrown back, the thumbs strongly flexed, breathing rapid and superficial, pulse small, intermittent, and too rapid to be counted, and other evidences of approaching coma. I was told that Dr. O'Dwyer was going to operate on the child. I asked permission to remain and view the operation, supposing, of course, that it would be tracheotomy. The boy was placed in the nurse's lap, an assistant held the head; a gag was put into his mouth. Dr. O'Dwyer passed the index finger of his left hand back into the child's pharynx, while his right held an instrument shaped like a small steel sound of the Van Buren pattern carrying on its distal end a gold-plated oval tube four-sixteenths of an inch in its long diameter, and two-sixteenths in its shorter diameter, and one and a half inches in length, collared around the upper extremity except at the anterior curve of the oval. In this uncollared portion was a small eyelet armed with a long silk thread. This tube was carried along the doctor's finger into the pharynx. There was a spasmodic coughing, a reddening of the face, the sound-like instrument was immediately withdrawn without the tube, the boy gave a long, deep inspiration, the thread was quickly withdrawn, and a marvellous change was instantly produced in the patient's whole condition. The intense redness caused by the first irritation gradually faded, a copious perspiration broke out over the forehead, the respirations became easy and quiet. I actually thought the child was dead; as the eyes were fixed in a stare of astonishment, and before the little sufferer had recovered from his amazement he was sleeping soundly.

As I watched him for an hour, the sleep was sound and deep, and only disturbed by occasional fits of coughing. His temperature at this time was 104°, pulse regular, 160, and the perspiration continued, but not so copious as at first. During that night the tube was coughed up, and immediately reintroduced; again coughed up on the following morning and again returned immediately. I saw him again on the thirteenth, immediately after he had coughed up the tube for the third time. At first the breathing was easy and quiet, but progressively growing difficult; at the end of twenty minutes it was painfully labored, the countenance became pale and anxious; in a piping cracked voice the little patient begged Dr. O'Dwyer to put the tube back, which the Doctor did, and again all the alarming symptoms immediately subsided. The tube remained *in situ* till the following day, the fourteenth, and was then immediately returned. Every effort to swallow liquids after the first introduction of the tube on the seventh, provoked violent coughing, solids and semi-solids were swallowed without difficulty. There has been a progressive improvement in the ability to swallow liquids, but they always provoke coughing. He can whisper quite distinctly, his pneumonitis is abating.

On the morning of January 13th I found in the croup ward, where the little patient just spoken of was domiciled, two other children suffering from severe inflammatory croup following measles. One was a little nurseling boy, thirteen months old. Measles had commenced ten days previous, croup had been progressing for twenty-four hours; the face was ashy pale, respiration superficial, with all the evidence of great obstruction. The child was unable to nurse, the mother held it in her arms and seemed greatly distressed. Dr. O'Dwyer directed the nurse to take the child into the adjoining room, and while there he introduced a tube, three-sixteenths by three-thirty-seconds, and one and four-tenths of an inch long. The operation was the work of a minute, the child was immediately returned to its mother, breathing quietly and relieved of all the distressing symptoms she had been so intently watching. She glanced hastily at the child, could see no disfigurement, no trace of blood, but the evidence of some great change which she did not understand. The child went to sleep in her arms immediately, and was only disturbed by occasional fits of coughing. At first the child could not nurse, but after twenty-four hours, it could nurse for five or ten minutes, with an occasional paroxysm of cough, but got plenty of nourishment.

The other patient in this room was a girl, four years of age, recovered from measles that followed whooping-cough. At this time she was suffering from quite extensive lobular pneumonia on both sides, croup had been progressing for twenty-four hours; the pulse was feeble, the temperature 105°, respiration was greatly obstructed, and in my opinion the child could not live many hours unless relieved from the great respiratory impediment.

In the absence of Dr. O'Dwyer, and in the great urgency of the case, Dr. Blodgett introduced a tube, four-sixteenths by two-sixteenths, and two inches long. I did not witness the introduction of this tube, but when I saw the patient the following day she was sleeping quietly, respiration being carried on without any difficulty whatever. I have seen one other patient in this institution wearing Dr. O'Dwyer's laryngeal tube. It is a boy six years of age, having extensive abscesses of the cervical glands, acute nephritis, following measles and scarlet fever, and pneumonia. The tube was introduced to overcome respiratory obstruction caused by œdema of the glottis. It was removed after twenty-four hours, but the patient begged piteously to have it reinserted. Although the tube was out only twenty minutes the boy was completely asphyxiated before the tube was returned. He rallied quickly and is now wearing it comfortably, but his recovery is somewhat doubtful, as the pneumonia and nephritis are still intense, and the patient refuses obstinately to take his medicine or stimulants, while the presence of the tube increases the difficulty of compelling him to do so. The only food he can be induced to take is ice-cream and condensed milk.

Previous attempts have been made to tube the larynx. In 1801 Dessault passed a tube through the nose and into the trachea, instead of the œsophagus as he intended. It was left there for several hours, and he only became aware of its situation when he began the injection of food through it. This accidental demonstration of the tolerance of a tube in the trachea for several hours suggested the propriety of treating laryngeal obstructions by a similar method. His first case was that of a man with some laryngeal affection; the catheter gave relief, but the man died the same day.

His second case was that of an adult with œdema of the glottis; the catheter was retained for a day and a half, and the patient recovered. These cases were reported by Bichat. In 1854 Dr. Horace Green created an intense excitement in the New York Academy of Medicine by his bold statement that he could swab out the trachea with a whalebone bougie armed with a sponge, and that he was able to pass a flexible tube through the larynx, and into the right or left bronchial tube at will, and inject strong solutions of nitrate of silver into tubercular cavities of the lungs. In 1858 Bouchut appeared before the Academy of Medicine at Paris, and advocated tubage of the larynx. He proposed the use of cylindrical tubes, 18 to 24 millimetres long and from 6 to 8 millimetres wide, introduced on the point of a hollow sound, and the tube allowed to rest on the vocal cords. A silken bridle was attached to the tubes to facilitate their withdrawal when necessary. He recited seven cases; five of them had died and two recovered after having tracheotomy performed. Notwith-

standing this unfavorable result of his experience, Bouchut, in commending tubage, declaimed against tracheotomy; consequently Trousseau, its strongest advocate at that period, condemned tubage, and Bouchut was never heard from again. Later, Schroetter proposed dilating the larynx through the mouth in chronic cases, using hollow, three-cornered vulcanized bougies.

Dr. Hack reports a patient with œdema of the glottis, in which case he introduced one of Schroetter's bougies, which gave relief. The bougie was removed and the patient was directed to go to a hospital, taking the bougie with him. On his way he was attacked with severe dyspnœa, and he himself introduced into his own larynx the tube that he was carrying.

In 1870 Weinlechner proposed the use of rounded tubes instead of the triangular Schroetter pattern, but he cites no cases. In 1880 Dr. William MacLean, of Glasgow, advocated the passage of a catheter into the larynx with the end protruding from the mouth to overcome respiratory obstruction from any cause. His cases are, first, a patient fifty-five years of age, in whom a surgical operation was performed. The catheter was passed into the larynx, one end protruding from the mouth; this was done to prevent blood flowing into the trachea during the operation. Second, a patient forty-two years of age, with œdema of the glottis; a No. 12 catheter was introduced and retained for thirty-nine hours, during which time the patient experienced no difficulty in drinking. Third, a patient, thirty-eight years of age, with œdema of the glottis; a No. 12 catheter was retained for thirty-six hours.

From the foregoing, which is all the testimony bearing on this subject which I was able to collect by a hurried search, it will be seen that Dr. O'Dwyer's operation of intubation of the larynx is not a revival of old methods. The nearest approach to his procedure was that of Bouchut, but the shortness of Bouchut's tubes, the shape, too, being cylindrical, and the fact that the tubes rested on the vocal cords and did not pass into the trachea, together with the additional fact that the tube was supported by a silken bridle, were evidences of the timidity with which Bouchut resorted to the procedure, and undoubtedly accounts for his total failure in the cases reported by him. Now Dr. O'Dwyer, on the other hand, uses a tube of sufficient length to drop into the trachea and reach a point as low, if not lower, than does the tube usually employed in the operation of tracheotomy. These he boldly introduces between the vocal cords with the upper flanges of the tubes resting on the cords. This tube is left *in situ* without any attachment whatever. By an instrument which he has designed he can remove the tube with the greatest facility.

Dr. O'Dwyer has been working on this subject for the past two years, but feels that he has not yet attained that pitch of perfection which he hopes some day to achieve; therefore I do not feel at liberty to describe the instruments he uses for inserting or withdrawing the tubes he employs, neither have I thought it right to ask him for his other cases, which he intends to give to the profession when he has perfected his instruments, and achieved that success which I am confident he will gain. From my own observation of the cases which I have cited, as witnessed by myself, I am fully convinced that intubation of the larynx is a more simple operation than that of tracheotomy; that the laryngeal tube is worn with greater ease to the patient; that the air which reaches the lungs is heated and moist, which is not the case with the tracheal tube; that coughing and expectoration are carried on with greater ease and more effectually than is possible with the tracheal tube, and that the absolute care and vigilant watching, which form such an absolute element of success in tracheotomy, are not called for in Dr. O'Dwyer's method of procedure. I may add that the most striking feature in this method, and which must be of the greatest comfort to the physician and to the parents, is the entire absence of mutilation or disfigurement. In the laryngeal diseases of infancy, which so often prove fatal under the very best conditions, parents and friends not infrequently imagine that it was the operation of tracheotomy that was the cause of death. The unsightliness of a dry, cracked mouth; the repulsive spectacle of a tube protruding from the trachea, often lined with, and having hanging from its orifice, expectorant matter; the necessity of informing the parents of the hopelessness of their child's recovery, and of requesting their consent to a desperate surgical operation as a kind of forlorn hope—all these painful elements are spared in the method adopted by Dr. O'Dwyer.

Mount Vernon, N. Y., January 20, 1885.

Clinical Department.

TRYPSIN AS A SOLVENT OF THE DIPHTHERITIC MEMBRANE.

Dr. B. M. Van Syckel, of 2091 Sixth Avenue, recommends a trial of trypsin as a topical application in diphtheria. Trypsin is one of the ferments of the pancreatic fluid. It will dissolve its own weight of fibrine in from five to ten minutes at a temperature of 37° Celsius (98.5° F.). It has been successfully employed as a solvent of the false membrane in diphtheria by Drs. J. Lewis Smith, of New York, and J. A. Keating, of Philadelphia, and at present several gentlemen are engaged in clinical experiments to determine its value for this purpose. Dr. Van Syckel has found that when the diphtheritic membrane, removed post-mortem, is immersed in a trypsin solution at a temperature of 37° Celsius, "it becomes transparent and slightly swollen, then breaking into fragments it is slowly dissolved, with the exception of a small residue consisting of cells and possibly bacteria. This settles to the bottom of the glass, leaving the solution slightly turbid and mucilaginous. In cases where the membrane is still adherent to the surrouuding tissue, the solvent action of the trypsin is slower, but no apparent change takes place in the healthy tissue." The solution is to be applied by means of the spray, applications being made every fifteen minutes if possible, or as often as the strength of the patient will permit, only a small amount of the liquid being used at each spraying. The importance of frequent applications should be impressed upon the parents or nurse, as upon this depends the success of the treatment. A leading pharmaceutical firm of this city is now employed in preparing a solution for use in diphtheria; but the writer states that the following extemporaneous preparation has been found very serviceable in his hands: 50 c.c. (℥ j. ℥ vj.) of a 1 to 1,000 solution of salicylic acid may be added to 5 grm. (℥ j. gr. xvij.) of "extractum pancreatis," and the mixture allowed to digest in a water-bath at a temperature of 37° Celsius (98.5° F.) for four hours, then filtered and made slightly alkaline by the addition of bicarbonate of soda. The solution should be made only as required, as it will not keep more than one or two weeks.

TELESCOPIC CATHETERIZATION.

Dr. A. E. Dugas, of Augusta, Ga., sends us an account of a method employed by him in cases of retention from so-called impermeable stricture of the urethra. He takes the largest size I gum-elastic catheter which will enter the meatus, passing it down until arrested at the narrowed portion of the urethra. It is then withdrawn, cut off just above the eye, the edges smoothed off, and then reinserted. When it has passed as far as it will go the end is cut off about an inch from the meatus, and the rest of the tube tied so as to prevent slipping from the canal. Now another catheter is chosen of a size that will just pass through the one *in situ*, and is inserted as far as it will go. It will probably pass farther than the first one, but if not, a smaller size must be selected. If this do not enter the bladder it is to be passed as far as

possible, and then the eye cut off as in the first case. Now a third catheter passed through number two will almost surely enter the bladder, except in the very worst cases. The larger or outer instruments serve, Dr. Dugas states, not only to ward off and exhaust the contractions of the urethra, but also act as a stiff handle to direct and guide the smaller and more flexible instruments passing through them.

In connection with this subject the writer states his belief that a great many more cases of retention of urine are due to some slight derangement of the kidneys than to the urethra. And he says that he has "frequently relieved such cases like magic by a dose of nitrate of potassa, say ten or fifteen grains, twice a day or oftener. The trouble is not that there is too much water in the bladder, but that what water is there is very irritating, and the urethra being more or less strictured revolts against its passage."

ILLUSTRATIONS OF THE INFECTIOUS NATURE OF ACUTE PNEUMONIA.

Dr. C. H. Smith, of Kenton, O., writes that a boy, aged eight, son of a farmer, died of pneumonia on March 25, 1882. A young man, aged twenty, who had helped nurse him was, in about a week, attacked with pneumonia and died. His mother, who nursed him, was also soon taken and died. A young lady who was in the house was attacked at about the same time and died. Some four or five others who were about at the time had mild types of the disease, but recovered. The cases were for the most part attended by homœopaths. Dr. Smith seeing some of them for a time.

Our correspondent writes that in 1870 he treated a boy, aged seven, suffering from pneumonia. He recovered. The father and mother contracted the disease, the former dying. Three other persons who had been about the house took the disease also, one only dying. In these cases the pneumonia was of a low type, and convalescence tedious. Dr. Smith did not note anything unusual about the season or the house in these latter cases.

VESICAL AND RENAL CALCULI—OPEN URACHUS—LITHOTOMY.

Drs. A. C. Benedict and E. M. Hermance, of Yonkers, N. Y., report the following very curious case: A carpenter, aged forty-three, suffered for several months from symptoms of vesical calculus, but would not allow the passage of a sound in order to verify the diagnosis. As the difficulty in urination increased it was noticed that some of the water was passed through the umbilicus, and it continued to pass in this way in small quantities for nearly a year. Finally the distress became so great that an examination was consented to; a stone was felt in the bladder, and the patient was admitted to St. John's Riverside Hospital for operation. Lateral lithotomy was performed and a slightly flattened egg-shaped stone, weighing two and three-fourths ounces, and measuring one and three-fourths by two and three-eighths inches, was removed entire. Convalescence was retarded somewhat by an intercurrent attack of epididymitis, but the patient finally was so far recovered as to leave the hospital and return home. At this time there was but a very slight exuding of urine from the umbilicus. About six months later the patient returned complaining of the same symptoms as before. No stone was detected by examination with the sound, and a diagnosis was therefore made of chronic cystitis. Despite appropriate treatment the patient failed steadily and died about three months later. At the autopsy the kidneys were found to be enlarged and to contain calculi. Upon incising the organs pus flowed out. About a dozen abscesses were found in each kidney, and also seven calculi, three of which were the size of a pigeon's egg. The ureters were enlarged. The bladder was of normal size and the mucous surfaces were healthy, but the walls were very much thickened. The urethra was normal. The urachus was pervious from the bladder to a point within an inch of the umbilicus, and thus the escape of urine from the umbilicus was explained. The nucleus of the calculus which had been removed by operation was the size of a filbert, and was made up of two different kinds of hair, viz., coarse dark hair and fine light hair. The question is how the hair was introduced into the bladder, and also whether the vesical or the renal calculi were first formed.

THROMBOSIS OF THE BRONCHIAL ARTERY.

Dr. S. E. Campbell, of Bay City, Mich., reports the case of a woman, sixty-five years of age, of previously fair health, who was suddenly seized, shortly after retiring for the night, with a severe pain in the left elbow passing up the arm into the chest. She also felt very cold and could not get warm until after several hours. When first seen, thirteen hours after the pain began, she was sitting up in bed. The pulse at the right wrist was strong and regular, but no motion was perceptible in either the radial or the ulnar arteries in the left side. The heart-beat was regular, and no bruit could be detected. Respiration was clear over all parts of the lung, but was somewhat jerky. The pain in the left arm was increased by pressure over the point of bifurcation of the brachial artery. A diagnosis was made of embolism of the brachial artery. The patient continued to sink, and died twenty-two hours after the commencement of the attack. The mental faculties were preserved until the end. At the autopsy a firm clot, about one and one-eighth of an inch in length, was found occluding the brachial artery at its bifurcation, and extending a short distance into the radial and ulnar branches. The heart was normal in size and appearance, and was surrounded by but little fat. A small cyst was found behind the bladder containing nearly an ounce and a half of thick, creamy pus. No previous history could be obtained beyond the statement that the patient had complained at various times of pains in the larger joints, and that she was not very strong. Dr. Campbell suggests that a case of occlusion of the arteries of the left arm with pain radiating into the chest might readily be mistaken for angina pectoris. And he queries whether, in the case related, death did not occur from shock.

TAPEWORM TREATED SUCCESSFULLY BY CHLOROFORM.

Dr. J. Walter Wood, of Port Richmond, S. I., has had an instructive experience in the chloroform treatment of tapeworm. The patient, a boatman, aged twenty-four, had suffered from diarrhœa and frequent desire to defecate. As he could not stop work, Dr. Wood directed him to take nothing but milk the following day, and nothing at all after 2 P.M. At 9.30 P.M. he came to the office, and was given two grains of calomel and immediately afterward one drachm of Squibb's spirit of chloroform in three ounces of mucilage of acacia. He was then directed to lie down, and in ten minutes was in a profound stupor from which he could not be aroused by shaking. The pulse, which was formerly seventy-two, was now reduced to forty. At the end of half an hour, electricity was applied and the patient aroused sufficiently to permit the administration of three drops of croton-oil enveloped in vaseline. He then relapsed into his former state and could not be permanently aroused until an hour had passed from the time of taking the chloroform. He complained of headache, staggered when attempting to walk, and compared his sensations to those of a man recovering from a debauch. Half a grain of podophyllum was then given, and the man allowed to go home. He was directed when going to stool to use a pail half filled with

water so as to avoid breaking the worm, and not to disturb the contents of the vessel. At a quarter past two o'clock in the morning a tape-worm measuring twelve feet in length was passed entire. Dr. Wood states that he shall in his next case use a much smaller quantity of chloroform.

Progress of Medical Science.

Intermediate Hospitals for the Treatment of Acute Mental Diseases.—The nervous system has of late years claimed the attention and study of the best medical minds of all countries, and it is now an evidence of a still further progress in this direction that mental diseases are no longer allowed to remain in the hands of asylum superintendents, but are beginning to demand the care and investigation that they undoubtedly deserve from a larger and more active class of specialists. It is by the medium of this development that Dr. John Van Bibber, of Baltimore, has been led at various periods, during the past five years, to investigate the plan of treatment and the management of insane asylums, both in this country and in Europe, the results of which are given in the January number of *The American Journal of the Medical Sciences*. It is a curious tradition, which is blindly accepted by most people, that insanity differs entirely from any other form of disease; that it must be removed from sight, and, if possible, from remembrance, and treated only by medical men who live within the walls of an asylum, and devote their lives to the care of this class of patients. No less is it a matter of general belief that the institutions in which this malady is treated are not hospitals, but asylums; that their use and purpose, though known, are in some way mysterious, and that their existence stands outside and apart from the ordinary ministrations of men. This uncanny reputation is clearly the result of prejudice, and to some extent the result of the present system of treating and caring for a most unfortunate class of sufferers. It is the remnant of that feeling which, years ago, built prisons for the safe-keeping of lunatics, and which employed chains and manacles in the treatment of their disease. We have developed safely beyond that dark period, and, with rare exceptions, we have even passed the epoch of restraint. But there are other changes which are as necessary and imperative to secure the better and more successful treatment of cases of acute insanity. These changes must affect many of the characteristic arrangements of insane asylums, the medical officer in his double rôle of physician and superintendent, and the crowding of large asylums with acute and chronic cases. This reform must also bring about the establishment of intermediate hospitals for the treatment of acute cases, and the gradual development of large asylums into homes for incurables and chronic cases. These points Dr. Van Bibber ably discusses separately and in detail, and he comes to the conclusion that many of the evils to be complained of in our asylum system arise from the unwise association of the curable with chronic cases, and the remedy is to be found in the establishment of the intermediate hospital, which is to stand between acute insanity and the asylum. This is the hospital which is to develop the ambition of the specialist, which is to enlarge his horizon, and to bring him out of an asylum into the active world of thought and progress. This is the hospital which is to teach the treatment of insanity as it has not yet been taught, and to educate, under active clinical instruction, the men who are to be the guardians and promoters of a most important reform. The possibility of making a hospital and a school out of what has been heretofore an asylum without educational power, or without the means of using valuable clinical material, is a proud future to look forward to. It means much to the profession. It is of deep significance to the public. It means an assurance that patients confided to the care of the intermediate hospital are to have every advantage of active treatment and good nursing. It means a course of treatment which will divert and distract the patients as much as possible from their sufferings, forcing them by activity to brood as little as possible over the dreary melancholy of their disease. It means the exclusion of every factor that can militate against the recovery of a patient, and the least possible detention after recovery.

Introspective Insanity.—Among those vague conditions of mental weakness in which there is slight derangement of the intellectual powers, yet a decidedly marked enfeeblement of the will, and an excitement of the emotions of a more or less limited kind, we find a variety of interesting psychoses which have, within a comparatively recent period, been considered under the names *folie du doute* or *grübelsucht*. In a clinical paper in *The American Journal of the Medical Sciences* for January, Dr. A. McLane Hamilton treats them under the title of "introspective insanity." In the cases Dr. Hamilton relates there was a history of insanity, and the nervous temperament was manifested by various peculiarities, more often by a species of hypochondriasis, by peculiarities of temper, and by acts of eccentricity which caused the subjects to be looked upon as "queer." These terms are applied to the condition of mind which is manifested by a morbid feeling of doubt and consequent indecision under the most ordinary circumstances, when both the doubt and indecision are unreasonable in the extreme, but the individual, under the mandate of an imperative conception, yields more or less to his disordered emotions. Some years ago we would speak of this condition of mind as "hysteria," or, if it influenced the patient's conduct to any remarkable degree, we would be at a loss for a proper explanation.

Psoriasis—Verruca—Epithelioma a Sequence.—Dr. James C. White, of Boston, in the January number of *The American Journal of the Medical Sciences*, presents brief notes of two remarkable cases of disease—cases extraordinary not for the rarity of the pathological processes they represent, but for the very unusual sequence of tissue-change exhibited in their course. There were three distinct pathological affections of the cutaneous tissues: psoriasis, verrucous hypertrophy, and epitheliomatous new growth; not occurring independently of each other, but as successive, mutual transformations in the above order. The three dermatoses which enter into the clinical history of Dr. White's case, and which are in their nature apparently as unlike as their companionship is rare, have a close affiliation in their anatomical relations. The transformation of patches of psoriasis into horny or warty permanent growths is not referred to in most works on dermatology as of possible occurrence even; the transformation of verrucous growths into epithelioma is of not very infrequent occurrence; but the uninterrupted sequence followed in this case, psoriasis, verruca, epithelioma, or, in other words, psoriasis as a cause of carcinoma, is extremely rare or unparalleled in dermatological history. The practical lesson to be deduced is that the transformation of patches of psoriasis into verrucous hypertrophy must be regarded as an ominous occurrence, and that the softening or other change of such horny growths demands thorough excision without delay.

Chloride of Lime was formerly used in gonorrhœa, but quite lately has been very warmly recommended as an injection in old cases of gleet after all the inflammatory symptoms, especially the pain, have subsided. The amount of secretion which may be present is a matter of no importance. Nothnagel says his experience with it has been favorable, in solutions of five to ten per cent.

Benzoic Acid.—A good pill can be made with five grains and one minim of glycerine. This is a convenient way for giving it in phosphatic deposits.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 21, 1885.

THE REVIVAL OF OVARIOTOMY.

A MEMORABLE address was recently delivered before the Midland Medical Society by Sir Spencer Wells, Bart., on "The Revival of Ovariotomy and its Influence on Modern Surgery." No American surgeon can read the literature of this subject without a thrill of pride in the recollection that the pioneer in this now broad path of operative work was a product of our own soil, with our national energy, and yet, in the words of his biographer, Dr. Gross, "cautious, calm, and firm." Nearly a century ago Ephraim McDowell was a humble disciple at the feet of John Bell in Edinburgh. He heard portrayed the hopeless character of ovarian tumors when left alone, and the empty results of the prevailing treatment by tapping, pressure, and injection. Hints had been thrown out from time to time that these tumors could be removed. His illustrious preceptor emphasized these suggestions, and portrayed to the pupil an ideal which the latter's genius was to make a reality. The seed of thought was carried back to the Kentucky home. It lay germinating for fourteen long years and then burst into full flower, Ovariotomy had been successfully performed.

That McDowell was the first ovariotomist, Sir Spencer Wells frankly admits. He gives, however, and justly too, due credit to the Hunters and Bell for their conception of a work which later decades were to see accomplished. Sixty years ago the operation began to take root in the soil of the mother country. It was carried on in a desultory manner and with disheartening results. Before the days of anæsthesia, and when the mortality percentage after all operations was large, it was indeed little less than "deliberative and tedious eviscerative vivisection." The introduction of anæsthesia benefited the situation but little. The theory of the operation seemed rational in conception but disproved by results attained. There was no one to champion the cause, eliminate its errors, and bring victory out of seeming defeat. In 1858 Sir Spencer Wells set out on his mission of rendering ovariotomy a justifiable surgical expedient. The struggle was long and severe. Results of former work were disheartening in the extreme. Frowned upon by the medical press and societies, traversing unknown paths without the beacon-light of experience, step by step he fought his way along, and, after eight years of unremitting toil, placed ovariotomy among the justifiable expedients of operative surgery, and, concerning the result, he could truthfully say "*et quorum pars magna fui.*"

The thorough appreciation and enjoyment of the address require some acquaintance with its author's work on "Ovarian and Uterine Tumors," of which it is, within certain limits, a corollary. It is always interesting to trace the development of an operation, and to note how the cherished expedients of one epoch have been the discarded methods of the next; how the various details of operative technique have been modified and improved in the light of experience. So with ovariotomy. The ligature, at first discarded, has now almost entirely superseded the clamp. Coarse whip-cord sutures have been abandoned and pure silk ones substituted therefor, and the tied pedicle returned to the peritoneal cavity. The length of the incision in the abdomen has been lessened, and in the closure of the latter the peritoneal apposition has become one of surface to surface instead of edge to edge as formerly. Careless preparation has given way to elaborate detail, and hap-hazard environment to rigid cleanliness and antisepsis. Thus steadily the mortality has lessened and order and light have come out of chaos and gloom. We are apt to forget that our predecessors groped painfully about after facts which to us are as plain as the sunlight. True as this is of all scientific research, it particularly obtains in the case of the subject before us. The deductions of Sir Spencer Wells, from his experience of twenty-five years, are full of interest. His preference for methylene bichloride as an anæsthetic will probably seem quite strange to some of us on this side of the Atlantic. His assertion that obstetric work and operative gynecology should not be done in private practice by the same surgeon but reflects his high conception of the calling of the specialist, but in view of recent successes in our metropolitan hospitals, this assertion needs modification. The results of his work simply show the power in the world of a man with a mission. His efforts in the revival of ovariotomy have not been those of a heedless enthusiast. The highest good of the patient has always been his aim. Palliative measures have been employed where they seemed to promise relief, and no operation has been undertaken unless fully justifiable. His opinions have been assailed. "Some," he says, "stand their ground, others have had the common fate of all fallacies;" but the soundness of his views is vindicated by his splendid results. In the last hundred cases of his series of a thousand, finished in 1880, but eleven deaths occurred and subsequent results have been even more gratifying. The effects of this wonderful success on modern surgery are wide-reaching. The forbidden ground of a quarter century ago is the broad highway of to-day, and we are almost overcome with the thought of what achievements the dawn of a new century will witness in this branch of the healing art.

MEDICAL MANNERS.

MR. EMERSON has said that, "manners are the contrivances of the wise to keep fools at a distance." It would hardly be fair to say that the manners of the wise physician are contrivances for an opposite purpose. Nevertheless the bearing and conduct of the doctor are important elements in his professional success. In this country, where we are all, according to Mr. Arnold, of the type of the lower English middle class, but according to our own

belief, simply men and women without class, the manners of the physician are best guided by some very plain general principles. If these manners indicate kindness, dignity, firmness, and self-respect, minor details of conduct will be very likely to arrange themselves harmoniously so as to cause no offence.

This appears not to be the case in England, where social distinctions are sharply drawn and rigidly adhered to, and where some few doctors only are gentlemen by virtue of their degree, while the rest are only "medical men" by virtue of their license.

An exquisite illustration of what interesting complications this produces is found in a letter, from "a practitioner of fifty-one years' standing," in the *Medical Times and Gazette*. This venerable correspondent desires to instruct the young medical man, who has settled in a "good neighborhood," how to conduct himself in the houses of the great to which he may be summoned. Beginning at the very beginning, he states that such houses have two bells and a knocker. "Which," he asks momentously, "should the physician choose?" We hang breathlessly upon the words of his answer.

"My own practice has been to ring the visitors' bell gently, though even that, when calling to see one of the servants, has seemed to me to savour of impropriety. But whatever course the young doctor may choose, let him, above all things, beware of using the knocker. That would imply a familiarity with the family, the very suspicion of which it behooves the circumspect practitioner to avoid. So long as he confines his manipulations to the bell-handle he is safe."

This seems to be satisfactory, but we would recommend, as in some cases preferable, the American practice of not ringing at all, but tossing a pill gently against the second-story window until attention is attracted. If this fails, a favorite practice in the far West is to place the foot firmly against the door post and wrench off the door-bell which is immediately thrown at the butler when he arrives. It produces an impression of decision of character and of having a large business.

Our English medical Chesterfield, however, next takes up a more important problem, viz., "What to do with the hat?"

"Following the custom of other men who have business in the house, he should by rights leave it in the hall, not on the floor, but on the hall-table. This course, however, may involve him in serious danger. If there are children about the house, they may be counted upon to play with it, perhaps to march into the drawing-room with it on their heads—a complication which, I need hardly say, as being evidence of undue familiarity, would be of the gravest import. My own plan has always been to take my hat with me, and only to relinquish it when the clinical investigation of a case rendered such a course absolutely necessary."

Here we think the advice given, though eminently logical, shows a little lack of breadth of thought and largeness of experience. Evidently the doctor should have left his hat on the floor—he seems to be that kind of a man. Failing in this, however, we should recommend to him and his fellow-souls the American plan of placing the foot gently in the bottom of the hat and drawing it up over the leg. Thereby all difficulties are solved.

The question of hand-shaking finally receives a masterly illumination:

"The ethics and etiquette of hand-shaking form a most difficult subject. As a rule, I agree with the *Lancet* that it is best to avoid it. If a lady of title offers two jewelled fingers, the young practitioner would be at once foolish and rude to decline to take them, but the touch should be cold and momentary. With the wives of commoners it will be best, if it can be done without obvious rudeness, to bow formally, instead of offering to shake hands, both on entering and leaving."

The doctor does not say what should be done with the cane, but it is easily understood that he simply passes it down his back in order to give proper formality to the bow which accentuates his entrance and his exit. As to what to do with the hands, it is a very easy inference that the doctor keeps his fingers in his mouth and is led out by the waiter.

We trust and believe that not many English doctors are like the correspondent of the *Times and Gazette*. And we can congratulate the profession in this country that we are not dependent upon "manners," but have a broad stretch of ocean as a contrivance to keep such people at a distance. Perhaps the American physician is not always "as good as anybody," but he is always so treated in his professional relations, and the query whether some one else is a social superior or inferior is the last thing that disturbs his thoughts.

THE VALUE OF POPULAR DISINFECTANTS.

We recently called attention to the change in view which has been going on regarding the value of various popular disinfectants. Some interesting additions to our knowledge of these substances have recently been made in the preliminary reports of the Committee on Disinfectants of the American Public Health Association.

The reports so far made have been three in number, and include tests of chlorine, bromine, and iodine, by Dr. George H. Rohé; of commercial disinfectants in general, by Dr. George M. Sternberg; and of the hypochlorites, by Dr. J. R. Duggan.

The committee define a disinfectant as an agent capable of destroying the infective power of infectious material, and the biological test upon known disease-germs and allied organisms was adopted.

Regarding chlorine, bromine, and iodine, as disinfectants, the following conclusions are reached:

1. Chlorine is an efficient disinfectant when present in the proportion of 1 part in 100; provided the air and the objects to be disinfected are in a moist state, and the exposure continues for upward of one hour.

2. Chlorine, when used in sufficient concentration to act as a trustworthy disinfectant, injures colored fabrics and wearing apparel.

3. Bromine is an efficient disinfectant in the proportion of 1 part in 500; provided the air be in a moist state, and the exposure continues for upward of three hours.

4. Iodine, in solution, is an efficient disinfectant in the proportion of 1 part in 500; the exposure continuing for two hours.

5. The use of chlorine, and in a greater degree of

bromine, requires considerable experience in management; when carelessly handled they may cause inconvenient or even dangerous symptoms in persons using them; for these reasons they are not suitable as disinfectants for popular use.

In testing the various commercial disinfectants "broken-down" beef-tea containing spores of *bacillus subtilis* and *bacillus anthracis* was used. Dr. Duggan, working with Dr. Sternberg, obtains the following interesting table of results:

LIST OF COMMERCIAL DISINFECTANTS TESTED.

Name upon label.	Per cent. in which active.	Per cent. in which failed
Little's soluble phenyle	2	1
Labarraque's solution	7	5
Liquor zinci chloridi (Squibb's)	10	7
Feuchtwagner's disinfectant	10	8
Phenol sodique	15	10
Platt's chlorides	20	15
Girondin disinfectant	25	15
Williamson's sanitary fluid	25	20
Bromo-chloralum	25	20
Blackman disinfectant	30	20
Squibb's solution of impure carbolic acid (about two per cent.)	..	50
Burchardt's disinfectant	..	50
Phenol sodique	..	50
Listerine	..	50

Regarding these disinfectants Dr. Sternberg adds: "Returning to the disinfectants in our list, it will be seen that all but the four last-named are efficient in various amounts, ranging from 30 to 2 per cent. But the relative value of the agents as here given does not establish their comparative practical value as disinfectants. Questions of cost, physical and chemical properties, etc., come into the account which it is the province of other members of our committee to consider. The agent at the head of the list, for example, notwithstanding its superior germicide power, does not seem to me to be as useful as some of those below it, on account of its insolubility and comparatively high price.

"We have nothing to say against the use of any of the agents in our list as antiseptics or as deodorizers. No doubt all of them are more or less useful for this purpose, and we have no desire to restrict their use. But the exaggerated claims made in relation to the germicide or disinfectant power of certain of these agents may do immense harm."

The time-honored Labarraque's solution receives much commendation from the committee. Dr. Duggan, as the result of a special examination of the hypochlorites, finds that a solution containing 0.25 of 1 per cent. (1 part to 400) of chlorine as hypochlorite is an effective germicide even when allowed to act for only one or two minutes, while 0.06 of 1 per cent. (6 parts to 10,000) will kill spores of *B. anthracis* and *B. subtilis* in two hours.

He adds that "the value of the various commercial preparations, such as Labarraque's solution and bleaching-powder (chloride of lime), of course depends on the amount of available chlorine they contain, since the chlorides and chlorates are of very little value as disinfectants. Bleaching-powder usually contains from twenty-five to forty per cent. of available chlorine. For most purposes a solution containing 1 part of this preparation to 100 of water is strong enough, for this will contain from 0.25 to 0.40 of one per cent. of chlorine as hypochlorite. As is stated above, the smaller of these quantities is sufficient to destroy spores almost instantly. There are very few purposes to which disinfectants are applied that are not fulfilled by this solution of one to one hundred of bleaching-powder. It is not poisonous, does not injure clothing, bedding, etc., and is almost without cost, since bleaching-powder is worth only about five cents per pound. The sodium salt furnishes in some respects a more elegant preparation, since it leaves on evaporation sodium chloride instead of the hygroscopic calcium chloride. If prepared according to the United States Pharmacopœia, it does not keep very well, but when made by passing chlorine gas into a solution of an excess of caustic soda, it shows very little tendency to undergo decomposition."

It will certainly be a matter of much congratulation to find that, after all, the cheapest and most harmless disinfectants are the best. We believe, however, that in practice the profession has already advanced still further than this, and has learned that, after all, plenty of fresh air and pure water are better than any disinfectants.

FIRE IN INSANE ASYLUMS.

THE Rev. Henry Ward Beecher is reported to have said, more or less facetiously, that the best solution of the insane asylum problem was to stand all the chronic lunatics in a row, and shoot them. The precious gentlemen who manage our insane asylums politically and scientifically, seem to have adopted a heated form of the Beecher policy. Within a comparatively short time, we have had to report the partial or complete destruction by fire of four insane asylums. In the last and most serious conflagration, that of the Insane Department of the Philadelphia Almshouse, the lives of twenty or thirty inmates were lost. Perhaps insane asylum managers think that the life of an insane pauper does not rate high, for it takes at least a dozen of them to support a politician. We do not, however, believe that the plan of cremating the insane is wise, human, or in the end even economical. Can not the learned body of Insane Asylum Superintendents, whose liberal spirit and scientific attainments are the source of so much pride, direct its energies toward the subject of fire departments? It is a shame to our institutions that such frightful accidents have so frequently occurred.

THE DIAGNOSIS OF PREGNANCY DURING THE EARLY MONTHS.

PROFESSOR HEGAR mentions a sign of pregnancy by which he claims the diagnosis of pregnancy may be made with certainty quite early. It consists in a peculiar softness, subtileness, and thinning of the lower segment of the uterus. By this is meant that part of the organ which is immediately above the insertion of the sacral uterine ligaments. The condition can be made out more readily when the uterus is elastic and soft, but also with ease when it is in its usual resistant condition. It is possible, by depressing the lower part of the uterus, to distinguish it from the superior portions and from the rigid cervix. The softness of this part might lead one to believe that the cervix was simply in contact with an abdominal or pelvic tumor.

The author knows of no pathological condition of the uterus which presents similar symptoms. The fact that the inferior segment of the uterus becomes during pregnancy the finest, softest, and most elastic portion, accounts for this remarkable sign. By practising rectal touch with conjoined abdominal palpation, it is possible to feel between the fingers this portion of the womb and thus ascertain its characteristics.

The *American Journal of Obstetrics*, October, 1884, published as a valuable sign in the very beginning of pregnancy the elevation of temperature to which the vagina, and more especially the uterus, are subject. During pregnancy the temperature of the interior of the uterus cannot, of course, be taken; but that of the vagina and, with some care, that of the interior of the cervix can be.

The normal temperature of the vagina is, as we know, 37.3° C. or 99° F., and it is found even early in pregnancy, according to Dr. Fry, that the vaginal temperature is 37.6°C. or 99.7° F., and that of the cervix 37.8° C. or 100° F.

With these two signs added to those already long familiar to the profession, there should certainly be little difficulty in deciding positively the existence of pregnancy in the early months.

GENERAL GRANT'S CONDITION.

THERE have been so many sensational stories concerning the precise character of the disease of General Grant's tongue and throat, that it will be gratifying to his many friends to learn that all the more serious and alarming symptoms connected with them have virtually disappeared. It was at one time feared, in professional circles at least, that the ulcerations of the tongue and fauces were dependent upon malignant disease, a not uncommon occurrence at his time of life, as the result of local irritation from a troublesome tooth. The focus of the trouble on the side of the organ, the usual site of cancer, and the induration of the base of the sore, were ominously confirmatory of such a suspicion. We are gratified to learn from his attending physician that all these signs of epithelioma have passed away, that the ulcerated surfaces have healed, and the adjoining tissues have regained their natural suppleness. There is now remaining only a small excavation in the neighboring tonsil, such as sometimes results from follicular inflammation of the part.

It would appear, from its clinical history, to have been a case of chronic superficial inflammation of the tongue, the long continuance of which results in progressive malignant destruction of the invaded parts.

There is a strong probability that excessive smoking was one of the prime factors as to causation, inasmuch as such has been proven to be the case in the large majority of persons so affected. The distinguished General would not certainly be considered an exception to this rule, affording as he does the "notorious example" for the anti-tobacconists. Still, it is fair to state that the disease sometimes occurs in those who do not smoke, and who are not inclined to any intemperance.

Whatever may have been the cause of the disease, it is a matter for great congratulation that all fear of grave complications are for the present at an end, and that our beloved ex-President is spared an affliction the bare contemplation of which would be distressing in the extreme.

News of the Week.

THE DEATHS FROM PATENT MEDICINES are estimated by a writer in the *British Medical Journal* to be about one hundred and fifty thousand annually.

THE EXPANSIVE IGNORANCE of our English critics is amusing. The editor of the *Medical Press and Circular* refers to a certain medical college in Georgia as a "Yankee Diploma Mill." No doubt our Southern brethren are proud and pleased to learn that they are "Yankees." It was not so twenty years ago.

THE PHILADELPHIA ALMSHOUSE FIRE.—Our esteemed contemporary, the Philadelphia *Medical Times*, can truthfully say, with regard to the recent burning of the insane department, "I told you so." In its issue of February 7th it concludes an article criticising this department with the words: "In the meantime, should a fire occur at Blockley, the Kankakee horror might be re-enacted at our very door."

TRYPSIN—ITS EFFECT UPON DIPHTHERITIC PSEUDO-MEMBRANE.—Dr. H. D. Chapin has lately been trying the effects of trypsin on diphtheritic pseudo-membrane, and considers that it opens a promising field for investigation. We hope in a few weeks to publish an article on this subject from the pen of Dr. Chapin.

MATERNITY HOSPITAL, NEW YORK.—Dr. Montrose A. Pallen has been appointed Consulting Obstetric Surgeon to this institution.

PROFESSOR BIRCH-HIRSCHFELD, of Dresden, has been appointed successor to the late Prof. Cohnheim, in the Chair of Pathological Anatomy at Leipzig.

ORGANIZING MICROBIOLOGICAL LABORATORIES.—The French Government has sent M. Dr. P. Gibier to Germany, in order that he may study the organization of the laboratories of microbiology.

THE FOURTEENTH CONGRESS OF GERMAN SURGEONS holds its annual meeting at Berlin, April 8 to 11, 1885, under the Presidency of Prof. v. Langenbeck.

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.—The classes at the Post-Graduate School this session are largely in excess of the numbers in attendance in 1883–1884. The greater number of the matriculates have taken tickets for three months. The hospital of the school is in active operation, and many important cases have been and are in its wards. An effort is being made to secure an endowment for the hospital.

PHILADELPHIA CLINICAL SOCIETY.—At the stated meeting, January 23, 1885, the annual election of officers resulted as follows: Dr. Edward E. Montgomery, President; Dr. John B. Roberts, Vice-President; Dr. Ida E. Richardson, Corresponding Secretary; Dr. L. Brewer Hall, Treasurer.

MICRO-ORGANISMS IN DISGRACE.—The following item, taken from an elaborate paper published in the *Medical Age*, sets the question at rest with a single blow: "The indisputable condition to the existence of phthisis is attributable to the undue waste or deficient supply of tribasic hypophosphorous acid in the nervous system." Selah!

New Haven Medical Association.—Officers for the ensuing year: Dr. M. C. White, President; Drs. W. O. Ayres and M. C. O'Connor, Vice Presidents; Dr. Henry Fleischner, Secretary and Treasurer.

Dr. Köhler has been appointed Director of the Imperial Board of Health of Germany, in place of Dr. Strück.

Doctors as Senators.—At the last election, Drs. Ch. Robin, Goujon, Cornil, Garrigat, Geo. Martin, Combes, and Libert were elected members of the French Senate.

Monevs for Hospitals.—The Distributing Committee of the Hospital Saturday and Sunday Association having concluded its labors, the following summary of the work of the Association for the year 1884 will be of interest. In spite of the hard times, had Hospital Sunday been fair, the collection in all probability would have equalled the aggregate of the year before, which was $43,062.74, while for 1884 it was $37,030.56. The designations by contributors to various hospitals, in so far as they came into the hands of the general treasurer, were as follows:

Institutions.	Amounts.
St. Luke's	$3,200 02
Presbyterian	1,700 99
St. Mary's	1,237 47
Home for Convalescents	187 91
Ruptured and Crippled	168 00
House of Rest for Consumptives	153 00
Manhattan Eye and Ear Infirmary	152 00
Home for Incurables	138 00
Hahnemann	116 28
Orthopedic	105 00
French	100 00
Medical College and Hospital for Women and Children	100 00
Skin and Cancer	85 00
Eye and Ear and Throat Infirmary, Harlem	84 12
Woman's	70 00
House of Holy Comforter	69 00
Mount Sinai	50 00
Harlem Hospital for Women and Children	42 35
St. Vincent's	25 00
Eye and Ear and Throat Infirmary, No. 2041 Fifth Avenue.	20 00
German	19 75
Trinity Infirmary	10 00
Infirmary for Women and Children	10 00
St. Barnabas's House	5 00
Harlem Dispensary	2 00
New York Hospital	2 00
Bellevue	1 10
St. Francis	1 00
Total	$7,856 99

Among the special designations sent directly to the treasurers of hospitals, and which are additional to the above, are the following: Presbyterian Hospital, $1,224.35; Lutheran Hospital, $312.24; Holy Comforter, $25.

After deducting all special designations and the expenses of the collections there remained in the hands of the Treasurer the sum of $24,000, which the Distributing Committee has apportioned among the various hospitals of the association, partly on the basis of free work and partly with regard to special designations, in which case deductions were made. The rule adopted was that in all cases where hospitals received $1,000 or more in special designations, they should receive twenty-five per cent. of such amount less from the undesignated fund than would otherwise be their share, and the amount thus accruing is divided equally among the ten hospitals lowest on the list as beneficiaries. The apportionment made (there being present of the committee Mayor Grace and Messrs. Jesup, Seligman, Cooper, and Brown) is as follows:

Hospitals.	Allotted by committee from undesignated fund.	Total receipts through the association.
Mount Sinai	$4,170 50	$4,220 50
St. Luke's	2,644 90	5,844 92
Ruptured and Crippled	2,923 68	3,091 68
Presbyterian	2,231 50	5,245 85
German	2,567 09	2,576 84
St. Mary's	1,063 97	2,301 44
House of Rest	934 02	1,087 02
Holy Comforter	915 02	984 02
Home for Incurables	898 73	1,036 73
Woman's	644 68	714 68
Orthopedic	651 64	756 64
Infirmary for Women and Children	641 26	651 26
French	566 42	666 42
Eye and Ear Infirmary	547 58	547 58
Hahnemann	539 90	656 18
Skin and Cancer	478 11	563 11
Ophthalmic	462 11	462 11
College and Hospital for Women and Children	453 39	553 39
Manhattan Eye and Ear	351 79	503 79
Ophthalmic and Aural Institute	313 71	313 71
Other institutions and expenses	.....	4,252 69
Grand totals	$24,000 00	$37,030 56

Frequency of Headaches.—About fourteen per cent. of all school-children may be expected to suffer from headaches, according to Liveing and a writer in the *Medical Times and Gazette.*

Sir Joseph Lister has received the order of knighthood *pour la merite* from the Prussian Government.

Bogus Dental Diplomas are being advertised in German papers, and sold through an English firm. They come from an alleged institute called the "Wisconsin Dental Academy," or "College."

Reviews and Notices.

The Influence of the Mind upon the Body in Health and Disease. Designed to Elucidate the Action of the Imagination. By Daniel Hack Tuke, M.D., F.R.C.P., LL.D. Second American from the Second English Edition. Philadelphia: Henry C. Lea's Son & Co. 1884.

The author of this work explains that one can, if he wish, term the book, "the influence of one cerebral state upon another." By this he shows that he recognizes the vagueness and somewhat unscientific character of the title which he has chosen to adopt. For since we do not know what the mind is apart from the body, since every mental state involves some organic bodily state, we might well say that in discussing the influence of the "mind" upon the "body" we must cover the whole of nervous and mental physiology.

Dr. Tuke's book has been before the profession now for twelve years. Since that time there has been considerable change in the manner in which medical men look upon the subject he has chosen. The author's compilation of cases was, we imagine, regarded as one of curious interest rather than of practical value. We are inclined to think that now, however, many will see with the author that the subject of the various and potent influences of the imagination upon bodily function is one concerning which every physician should be thoroughly cognizant. There is not a practitioner of medicine who,

if he is intelligent will not see and, if wise, utilize, psychical therapeutics. It is a *deus major* in his armamentarium.

The present edition of Dr. Tuke's work retains substantially the same arrangement as the first. The different chapters are devoted to the "Influence of the Intellect, Emotions, and Volition upon Sensation, Voluntary and Involuntary Muscles, and Organic Functions."

The "Influence of the Mind upon the Body in the Cure of Disease" is then discussed, and the indications for the employment of psycho-therapeutics laid down.

Dr. Tuke has collected a great number of illustrative cases, some of which we fear are not to be entirely credited.

Lectures on some Important Points connected with the Surgery of the Urinary Organs. By Sir Henry Thompson, F.R.C.S., M.B., London. Philadelphia: P. Blakiston, Son & Co. 1884.

The six lectures comprising this volume were delivered at the Royal College of Surgeons in June last. In a condensed form they have already appeared in many of our medical journals. In their present shape they will prove acceptable to all surgeons who wish to keep for reference Sir Henry's latest views on some important details of the surgery of the genito-urinary apparatus.

The Lock-Jaw of Infants (Trismus Nascentium); or, Nine-Day Fits, Crying Spasms, etc.: Its History, Cause, Prevention, and Cure. By J. F. Hartigan, M.D. New York: Bermingham & Co. 1884.

The principal point of interest in this monograph is in reference to the etiology of trismus neonatorum. The theory originally advanced by Dr. J. Marion Sims, that the disease is caused by mechanical pressure of the occipital or parietal bones on the brain and thence to the medulla and its nerves, is confirmed by the histories of forty-nine cases. In some of these cases, however, the author may have mistaken cause and effect. Thus the convulsions, by producing rapid atrophy with resulting shrinking of brain-tissue, may sometimes be the primary factor in displacing the bones. We suspect that in trismus we have often a pathological condition more complex than the author supposes, and the attempt to explain all cases by a single and universal cause will hardly be successful. At the same time the etiology advocated by the author is doubtless frequently operative. Much labor has been expended in compiling these cases, and the subject is presented in an attractive form.

The Science and Art of Surgery: A Treatise on Surgical Injuries, Diseases, and Operations. By John Eric Erichsen, F.R.S., LL.D., F.R.C.S., Surgeon Extraordinary to Her Majesty the Queen, Ex-President Royal College of Surgeons, England. Eighth edition. Revised and edited by Marcus Beck, M.S., M.B. London, F.R.C.S. In two volumes. 8vo, pp. 2,329. Philadelphia: H. C. Lea's Son & Co. 1884.

This last American edition is a republication of the eighth English edition recently issued in London. It appears in two large octavo volumes with nine hundred and eighty-four engravings on wood.

After being before the profession for thirty years, and maintaining during that period a reputation as a leading work on surgery, there is not much to be said in the way of comment or criticism. That it still holds its own goes without the saying. Many alterations and additions have been made, necessitated by the changes in surgical practice founded on advances in surgical pathology. The department of ophthalmology has been omitted. This saves much bulk in the work, which in one of its kind is a desideratum. Besides, ophthalmology is now so much of a specialty that it cannot be fairly represented in any way save by a separate and elaborate treatise. But what the work has apparently lost in this regard it has gained in many others, enabling the distinguished author to incorporate a correspondingly greater amount of material bearing more particularly upon the general science and art of surgery. To Mr. Beck, the Editor, has been entrusted the revision of the parts of the work bearing on surgical pathology, and he has performed his task in an admirable manner, presenting all the advanced views and the results of the most recent researches.

The author, still manifesting his bent toward clinical surgery, infuses into its principle his large experience and ripe judgment. Wedded to no school, committed to no theory, biassed by no hobby, he imparts an honest personality in his observations, and his teachings are the rulings of an impartial judge rather than the prejudiced views of a pleading advocate. Such men are always safe guides, and their works stand the tests of time and experience. Such an author is Erichsen, and such a work is his "Surgery."

The National Dispensatory, containing the Natural History, Chemistry, Pharmacy, Actions, and Uses of Medicines, including those recognized in the Pharmacopœias of the United States, Great Britain, and Germany, with numerous references to the French Codex. By Alfred Stillé, M.D., LL.D., Professor Emeritus of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania, and John Maisch, Phar.D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. Third Edition, thoroughly revised, with numerous additions. With three hundred and eleven illustrations. Philadelphia: Henry C. Lea's Son & Co. 1884.

Five years ago the first edition of this work was published. The present edition, which is now before us, forms a rather bulky volume, and while pharmacists will find it a valuable work of reference, the general practitioner will scarcely find it a necessary addition to bookshelves already groaning under the weight of more strictly medical manuals. As a dispensatory "embodying the pharmacopœias of the four chief civilized nations," it is to be recommended for its accuracy, its systematic arrangement, and the detailed comprehensiveness with which the subject is dealt with.

Conférences Thérapeutiques et Cliniques sur les Maladies des Enfants. Par le Dr. Jules Simon. Tome II. 8vo, pp. 316. Aux Bureaux du *Progrès Médical*, Paris. 1884.

This is a very practical work, consisting of a series of lectures, mostly devoted to the therapeutics of children's diseases. We cannot say that the author presents us with much that is new, but his views are evidently based upon wide experience, and the reader cannot fail to be profited by a study of them.

A System of Human Anatomy. By Harrison Allen, M.D. Philadelphia: Henry C. Lea's Son & Co. 1883.

Part VI. and last takes up the consideration of the organs of sense, of digestion, of respiration, and the genito-urinary organs. The general plan is the same as that of the previous parts: first, a description of the part under examination, then reference to variations from its usual formation, and finally remarks on its medical and surgical relations. Not only the gross but also the minute anatomy receives proper attention. The eye is first taken up, with its appendages; then follow the ear, the nose, and the tongue; the skin is described among the excretory organs. The organs of digestion and of respiration, as well as the genito-urinary organs, are described in the usual sequence.

It is difficult to conceive, for practical purposes, of a work more complete and clear than the one before us. The style is concise and pointed, and the information is brought down to date. Each portion of the body receives minute and exhaustive examination in such manner as to make the book equally useful to the specialist

and to the general practitioner. While, of course, the nature of the subject-matter precludes anything like originality, the text displays the profound learning and wide reading of the author. To criticise each part as its importance deserves would occupy too much of our space, and it would be unjust to select any one portion as an indication of the whole. The text concludes with well-written chapters on superficial anatomy and on embryology and teratology. The work ends with a very complete index, table of contents, and list of engravings.

The type is large and clear, the paper good, and the engravings are distinct and elucidate the text. There is but one fault to be found with the latter, and that is that in binding they have been (whether intentionally or accidentally) misplaced, so that the engraving of the relations of the thoracic viscera occurs in the midst of text on the kidney, and while reading about the capsule of tenon we are confronted with plates of the tongue and of the nose. But these slight defects can easily be rectified or allowed for, and the work as a whole must be regarded as a valuable contribution to the present state of our knowledge, and the most complete of American works on anatomy.

A Manual of Dermatology. By A. R. Robinson, M.B., F.R.C.P. & S. Edin. Cloth, 647 pages. New York: Bermingham & Co. 1884.

Dermatological literature appears to be keeping well abreast of that of other special branches of medical science. We are glad to see American authors contributing their share to the fund of knowledge. Although several works on skin diseases have but recently appeared in this country, so long as the new ones bear the mark of original and careful work, they will always be welcome. The manual before us exemplifies this view. For although to a great extent compiled from other sources, as such a work must needs be, it nevertheless reflects enough of the personal experience of the author to make it a desirable addition to the physician's library.

The original drawings show that pathological histology, a branch of dermatology too often neglected in American works on cutaneous diseases, has here received considerable attention.

The classification of hebra which is usually adopted in this country is made use of with some unimportant modifications. The treatment is quite up to date. On the whole, notwithstanding some omissions and defects, the manual commends itself to both student and practitioner as an elementary treatise on the skin and its diseases.

Handbook of Diseases of the Eye and their Treatment. By Henry R. Swanzy, A.M., M.B., F.R.C.S.I. Pp. 427. London: H. K. Lewis. New York: Appleton & Co.

The author of this handbook is to be congratulated upon the successful way in which he has completed his task. While the book is chiefly intended for students attending an Opthalmic Hospital, it is substantially a book of reference on ophthalmology, and in the course of its pages the views of the best authorities of the day on the subject are clearly set forth. The book is more than a compendium. While the special views of the author are nowhere given an undue prominence, the theories advanced and the lines of treatment laid down are based on careful study, and embody the results of personal experience.

The first three chapters on elementary optics, abnormal refraction and accommodation, and the opthalmoscope, afford the student a clear understanding on these subjects. In the study of diseases of the eye there is nothing that offers to the average student more difficulty than the question of refraction. In many of the textbooks a practical understanding of the theory of refraction and accommodation is rendered difficult and obscure by the frequent presentation of mathematical formulæ. A simpler treatment of the subject has been followed in the book before us, and since Landolt's excellent text-book we know of nothing as likely to give to the student a clear comprehension of this subject.

In the chapter on diseases of the eyelids, the author in describing ophthalmia tarsi, fails to allude to the very frequent connection in these cases between the marginal lid affections and errors of refraction of the eye, and in his remarks on the treatment of the ulcerative form of blepharadenitis nothing is said of the value of the mitigated stick of nitrate of silver in healing the ulcerations.

So, too, in the treatment of telangiectic tumors of the eyelids, the value of the knife in dissecting out the tumor might have received mention. In the treatment of distichiasis and trichiasis the various methods of operation are clearly stated and well illustrated by drawings. The surgical treatment of entropium includes the operations of Streatfield, Snellen, and Berlin. The American student will miss the ingenious operation of Green, of St. Louis, which perhaps in another edition of this work will receive the attention it deserves. The author's views on the use of probes in the treatment of stricture of the nasal duct seem to us deserving of especial mention. He rightly condemns the use of the large conical probes of De Wecker. He draws attention to the enormous dilatation of the passage into the sac by the attempt to pass a probe three to four millimetres in diameter through a passage which in the physiological condition is of a less calibre than this.

The chapter on treatment of ulcer of the cornea is well written, and the value of paracentesis of the anterior chamber is given the prominence it deserves as a remedial measure.

Sympathetic ophthalmology is given a conspicuous place in this handbook and the subject is presented in the light of the most recent observations on this most important subject. The views of the author in reference to the subject of enucleation are worthy of careful study and the rules he has here laid down in regard to surgical interference are clearly stated, and his generalizations are wise.

The chapter on the orbital muscles is clearly written and well illustrated; the presentation of the subject of dynamical strabismus is what we might expect from the author's earlier excellent paper on this important subject. On page 402, in his description of tenotomy of the recti muscles, the value of the conjunctival suture in closing the wound with a view to the avoidance of the annoying granulations is not alluded to. Its use is not, we think, a matter of routine but of positive value.

In the space allotted to a book review it is not possible at greater length to discuss the chapters on cataract, glaucoma, and affections of the optic nerve and retina. What we have said before might be said in reference to these divisions of the subject. The author writes in the light of the most recent investigation. With complete familiarity with the literature of ophthalmology, he has embodied in this book only that which has been accepted by the leading authorities, and through the entire work is constant evidence of a careful, conscientious, and thoroughly competent observer. We predict for the book a foremost place among ophthalmological text-books.

Modern Medical Therapeutics: A Compendium of Recent Formulæ and Specific Therapeutical Directions from the Practice of Eminent Contemporary Physicians, etc. By George H. Napheys, A.M., M.D. Edited by Joseph F. Edwards, M.D., and D. G. Brinton, M.D. Eighth edition. 8vo, pp. 629. Philadelphia: D. G. Brinton. 1885.

The eighth edition of this popular work is much enlarged and improved, and the general standard of practical excellence is creditably maintained. It has been written for the purpose of teaching the practitioner how to cure disease, giving the practical indications and particular remedies to that end. From these points of view it has an extended usefulness.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, January 22, 1885.

ALEXANDER S. HUNTER, M.D., CHAIRMAN.

THE old officers were re-elected for the ensuing year.

DR. L. EMMETT HOLT read a paper (see pp. 174 and 201) on

PNEUMONIA IN CHILDREN.

The discussion was opened by DR. J. E. WINTERS, who said that pneumonia, occurring in children, differed considerably from that met with in adults, unless the pneumonia of old people was excluded. In very many cases in children the onset was obscure, especially in those exhausted by previous disease, and in many cases it could not be diagnosticated by physical signs.

According to his observations, lobar pneumonia occurred in children more frequently in the months of December, January, and February than in any other in the year.

While lobar pneumonia occurred frequently, he should hardly be willing to say that it occurred by preference, in healthy children. He regarded exaggeration of puerile respiration as the important physical sign during the first twelve hours of acute lobar pneumonia, followed within twenty-four hours by bronchial breathing. He thought that the crepitant râle was scarcely ever heard in children. Pure bronchial breathing, he regarded as one of the most important physical signs of lobar pneumonia, and subcrepitant râles of broncho-pneumonia; subcrepitant râles especially at the margin of the area of consolidation. He had noticed that delayed resolution in broncho-pneumonia, as a rule, terminated in phthisis. Serous pleurisy, as a complication, occurred with both forms of pneumonia more frequently in children than in adults.

Dr. Winters regarded one-fiftieth of a grain of morphine every two or three hours, for children one year old, as too free use of the drug, and preferred opium and ipecac. He also spoke of belladonna, especially in broncho-pneumonia in children, as a useful remedy, both as a cardiac and respiratory stimulant. Instead of continuous poultices he preferred repeated applications of poultices containing a small quantity of mustard.

DR. A. JACOBI had scarcely any fault to find with Dr. Holt's paper, and only few facts to add. He would direct general attention to the fact that, in the lungs of children a certain amount of bronchial respiration could be heard normally, which might be mistaken for the bronchial breathing of pneumonia. There was also a certain amount of normal dulness over the lower lobe of the right lung, which it was well also to keep in mind.

With regard to convulsions, so far as he knew, they were more apt to occur in the beginning of pneumonia when the disease was located in the upper lobes, than when present in the lower lobes, other things being equal. As to the occurrence of lobar pneumonia, he believed it was true that, in the first months of life, it occurred in a much greater percentage of cases than it did in later months. Many severe cases of pneumonia, especially those which begin with convulsions, were mistaken for meningitis.

An important physical sign in diagnosis was the disturbed proportion between the heart-beats and the respirations. Normally the proportion was 37 or 38 to 10, and when this proportion was disturbed to much extent in a child, perhaps 37 or 38 to 15 or 20, it was almost positive evidence that there was inflammatory disease of the respiratory organs. There were many cases of lobar and of broncho-pneumonia which were complicated by interstitial pneumonia, or so called peri-bronchitis. These cases usually ran a protracted course, and sometimes without cough.

Was recovery so complete as Dr. Holt believed? There was one peculiar fact which seemed to prove that it was not, and it was that relapses were very frequent. With reference to treatment, Dr. Jacobi thought that there was no greater danger than the indiscriminate use of opium in pneumonia. Pain and dyspnœa were diminished, it was true, but the drug was also liable to paralyze, totally or partially, the respiratory muscles, and thus to prevent expectoration. If he was to give any rule, it would be, first, that no medical student or young practitioner should touch opium in the treatment of pneumonia. Not that he discarded opium entirely, because he frequently gave it, but only in occasional doses and simply to procure a short amount of sleep; as a rule, he did not use it in this disease. He regarded the occasional use of the iodide of potassium as very beneficial, especially in interstitial pneumonia, or either of the other forms complicated by the interstitial variety. In the second and third stages of such pneumonias, he used a good deal of the iodide of potassium, and he administered it on the general principles which would lead to its use in the treatment of any kind of disease.

DR. JOHN H. RIPLEY complimented the author on the excellence of his paper, based on personal experience and observations, and also agreed with Dr. Jacobi in the view that lobar predominated over broncho-pneumonia in very young infants. As to diagnosis, he thought the author of the paper had laid too little stress on the absolute necessity of reaching it by means of physical examination.

The statement made by Dr. Jacobi concerning the disturbed proportion between the pulse and respirations he accepted, but he had seen the proportion equally disturbed in malarial fever, and therefore this was a source of error which might be overlooked.

Dr. Ripley thought that greater stress should be laid upon cerebral symptoms in pneumonia in children, than had been done by either Dr. Holt or Dr. Jacobi, not only when the pneumonia occurs at the apex, but at the apex anteriorly. Eustace Smith had endeavored to belittle, in the last edition of his book, that observation, but, according to Dr. Ripley's experience, it was almost uniformly so. With pneumonia at the apex in front, there were cerebral symptoms such as might readily lead to the diagnosis of meningitis.

He also believed that there was a difference between capillary bronchitis and broncho-pneumonia, and that broncho-pneumonia was not a part of capillary bronchitis. He did not think that the subcrepitant râle was a physical sign of pneumonia, but a sign of bronchitis in the smaller tubes. If there was nothing except that upon which to base the diagnosis of pneumonia, it was not present. Crepitant râles were very common in children, even more common than in adults. Dr. Ripley had not found an excess of normal respiratory murmur in the beginning of pneumonia, but rather feeble and high-pitched respiration. Hence it was that beginners located pneumonia upon the wrong side, as a rule; they got it where there was the most noise.

He believed in the use of large hot poultices, covering the whole of the chest. They should be applied hot, not too soft, and changed every six hours.

With regard to internal treatment, he believed that as much could be done in cases of pneumonia as in almost any disease. He believed in the judicious use of opium, and thought that one-fiftieth of a grain of morphine was not too much; but he would combine it with a diaphoretic or an arterial sedative, as the liquor ammonii acetatis, aconite, veratrum viride, etc., and for opium he would use paregoric. If there was any drug which was useless, and worse than useless, unless the pneumonia was complicated by malarial poisoning, it was quinine, especially in heroic doses.

DR. J. C. PETERS was pleased to know that the treat-

ment of pneumonia had got back to near what it was forty years ago. He thought the time had come when stimulants and quinine were to be regarded as among the things of the past in the treatment of this affection, and hoped to see the time when general blood-letting would again be resorted to occasionally. He believed in the aconite treatment partially. The opium and ipecac treatment, he thought, was due to himself. He had preferred to iodide of potassium the simple liquor potass, or acetate of potash, and occasionally minute doses of mercury. He preferred pulsatilla to either belladonna or ipecac, especially in cases of slow resolution. He employed the oil-silk jacket, and was prejudiced against poultices.

Dr. W. P. Northrup had found ipecac especially useful in the treatment of both forms of pneumonia; codeia, also, was a useful remedy. He thought that when Dr. Ripley spoke of capillary bronchitis, only one-half of the name of the disease was given, for the smaller bronchi were infiltrated with inflammatory products, the epithelia of the air-vesicles were swollen, and the pleura had a dull, lustreless appearance, known as the sand-paper pleura, even in cases which had all the clinical features of so-called capillary bronchitis. He was almost ready to say that there is no such disease as capillary bronchitis.

In four hundred autopsies on the bodies of children who died of pneumonia, Dr. Northrup had not seen anything which presented the appearance of lobar pneumonia of adults. In the lungs of infants the capillaries play an important rôle. When these lungs were examined microscopically it was readily seen that the bronchi were large, and the alveoli small; that the interalveolar tissue was much greater in extent than in the adult lung, and the nearer the lung approached the embryonic state the more numerous were the leucocytes, which explained the predominance of pus-cells in the exudate. He had no hesitancy, therefore, in saying that there was a difference between the lobar pneumonia of children and that of adults. The blood-vessels of the alveoli were large and tortuous, presenting, in the normal condition, an appearance very much like that seen in the lungs of heart disease, and, therefore, he believed that many of the physical signs of pneumonia might be given by excessive congestion of these capillaries. The collapse of lung-tissue in children, as described by Jürgensen, Dr. Northrup believed was pneumonia, and the description given by that writer was misleading.

Dr. Billington said that his experience agreed with that of the author of the paper concerning the prognosis in lobar pneumonia of young children; and with regard to lobular pneumonia, it had been more favorable than appeared from the reports made by Dr. Holt and the other speakers. He believed that the judicious use of opium was beneficial. A favorite combination with him was one made of muriate of ammonia, ipecac, and paregoric. He also thought there was a class of cases in which quinine was an important remedy, especially those associated with sewer-gas poisoning.

Dr. Holt, in closing the discussion, said that, while he did not believe he had ever done any harm by the use of morphine as mentioned, he had substituted for it the tincture of opium with ipecac, as mentioned in his paper. In speaking of the physical signs of lobar pneumonia, he mentioned especially a circumscribed area of consolidation as a marked feature.

The Chairman announced that the paper for the next meeting would be read by Dr. H. E. Crampton, on "Inversion of the Uterus."

The Section then adjourned.

Glacial Acetic Acid dissolves almost all protein bodies, especially albumen and fibrin, but not casein. It, of course, destroys warts and corns.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 28, 1885.

John A. Wyeth, M.D., President, in the Chair.

Dr. T. Mitchell Prudden, from the Committee on Microscopy, reported that the specimen presented in behalf of a candidate by Dr. Carpenter at the last meeting of the Society was one of *colloid carcinoma*, thus confirming the diagnosis of malignant disease of the cæcum.

Dr. E. G. Janeway presented, in behalf of a candidate, a specimen of *chronic endocarditis with cerebral hemorrhage.*

Dr. W. M. Carpenter presented, in behalf of candidates, three specimens: (1) *Carcinomatous tumor*, removed from the anterior wall of the abdomen near the umbilicus, with peritoneal and omental attachments; (2) *intestinal ulcers* (typhoid); and (3) *fibro-myoma of the uterus*, which had undergone calcification.

Dr. T. Mitchell Prudden presented a specimen with the following history and pathological report:

MYXO-SARCOMA OF THE THUMB, FOLLOWING THE STING OF A WASP.

"I am indebted for the specimen and clinical history to Dr. Francis Bacon, of New Haven. The man from whom the specimen was taken was about sixty-three years old, well nourished and in sound general health. He said he was stung by a wasp—he thought by two wasps—in his thumb in August last. There was at the time, he thought, about the usual pain and swelling accompanying such a wound.

"The pain ceased, very much as it usually does in such cases; the swelling, however, never subsided, but steadily, at first slowly, latterly rapidly, increased without the slightest pain, until its removal in December.

"The tumor is altogether about as large as a butternut, is lobulated, and extends from the root of the nail back over the two last phalanges. It nearly completely surrounds but apparently does not involve the bones. In consistency it is soft, and before the removal of the skin it seemed almost fluctuating. The tissue of the tumor is gelatinous in appearance and of a dark color.

"In structure it is a spindle- and round-celled sarcoma, with a soft and abundant myxomatous basement substance.

"There are comparatively few blood-vessels in the tumor. Its dark color is due to a moderate amount of pigment contained in the cells.

"Structurally the tumor is of no unusual interest, but I present it on account of the rather striking nature of its immediate inciting cause. It belongs to that class of tumors which, although frequently enough met with, after all do not form such a very large percentage of all tumors—the class in which the commencement of the new growth is directly and evidently associated with some local injury.

"I do not suppose that the particular injury in this case is of any special significance, beyond the fact that it caused an inflammatory condition favorable to the production of new tissue of this kind.

"The association of the commencement of such a tumor with a definite injury, does not, I think, really throw much light upon their etiology."

Dr. E. C. Seguin presented a specimen of

SALIVARY CALCULUS,

which was discharged spontaneously from Steno's duct. The man from whom it came was a patient under general treatment for specific hemiplegia, and, without apparent cause, his right cheek began to swell in front of the parotid gland. When Dr. Seguin saw him in the evening, there was an indurated swelling opposite the molar teeth, and within the mouth he found the nipple-like projection of the mouth of the duct, from which he forced a number of drops of muco-purulent fluid. He directed the patient to bathe his mouth with hot water,

and, on awaking in the morning, he felt something hard, upon the inner surface of the cheek, which was the specimen presented.

Dr. Seguin had met with a similar calculus in Wharton's duct, in a lady of gouty habit. In that case he was able to make a diagnosis with the probe, but the calculus was thrown out spontaneously.

Dr. Beverley Robinson presented a specimen of

ACUTE LOBAR PNEUMONIA—CHRONIC DIFFUSE NEPHRITIS,

with the following history, furnished by Dr. King, House Physician at St. Luke's Hospital. Thomas H. W——, aged forty-four years, English, coachman, was admitted November 26, 1884.

No family history of phthisis. Patient has never had any previous lung trouble. Had acute rheumatism ten years ago. Denies indulgence in alcoholics.

Three days ago, after exposure to wet, he had a severe chill, followed by a fever and by severe pain in the right side of the chest; has, since then been confined to bed. There has been marked dyspnœa; the expectoration has been tenacious, and, at times, has contained blood; there has been some sweating. On admission, the patient was well nourished and not anæmic; tongue thickly coated; appetite poor; bowels constipated; pulse, 126; respiration, 40; temperature, 101.8° F. Urine: specific gravity, 1.013, slightly alkaline, albumen one per cent.; no sugar; microscopical examination—strings of mucus, some pus-cells and phosphates.

November 27th.—Tongue quite dry; pulse, 146, full, but soft and compressible.

Heart.—Inside and below the left nipple the heart-sounds were regular; no murmur with the second sound; slight murmur with the first sound, heard between the nipple and the sternum. At the base the heart-sounds were almost concealed by the respiratory murmur, but there are probably no murmurs.

Lungs.—Posteriorly, on right side, bronchial respiration as high as the spine of the scapula, and down to the lower third; no bronchial breathing at the right base. Over the upper limit of the bronchial breathing there were some crepitant râles on inspiration; breathing imperfect. At the right base there was some resonance, but absolute flatness on percussion above the right base (patient in left lateral decubitus); some egophony over the middle portion of the right lung, none heard in the axilla. Puerile or exaggerated respiratory murmur all over the left chest.

Temperature.—A.M.: 102.8° F.; pulse, 130. P.M.: 103.4° F.; pulse, 145; respiration, 33.

November 28th.—Died at 10.30 A.M., apparently from cardiac failure. Had a general convulsion just before death.

Post-mortem.—Body well nourished; rigor mortis well marked; no œdema. *Peritoneum* normal.

Diaphragm normally located on either side.

Thorax.—On the left side no fluid and no adhesions in the pleural cavity. Old adhesions everywhere, binding the right lung to the chest-wall, excepting posteriorly and near the left base, where there is about a pint of purulent serum.

Heart hypertrophied; visceral pericardium thickened in places; valves normal. Muscular tissue is darker than normal.

Lungs.—The left is congested and œdematous; the right is hepatized throughout, in places, the organ presenting the gray variety, in other places the red variety.

Spleen large and soft.

Kidneys.—The left smaller than normal; capsule everywhere adherent; the lower end of the kidney is occupied by a large mass of cheesy material; cortex thin; surface granular; pelvis dilated. Right larger than the left; upper end the seat of a large infarction, which, in the interior, has undergone cheesy degeneration. There are other cheesy foci in the kidney near this infarction; capsule adherent in places; cortex swollen; markings not distinct.

Stomach normal. *Liver*, common bile-duct pervious; contains excess of fat; there is a small cavernous angioma on its surface.

Bladder normal. *Urethra* admits large sound.

Pneumonia was diagnosticated; pleurisy was suspected, but could not be distinctly made out. The condition of the urine had not then been reported, and even had it been, its specific gravity only would have raised the suspicion that it was a case of granular kidney. Orders had been made for venesection provided that the heart's action—then very rapid—became irregular in force or frequency, but this had not occurred when an observation was made an hour before death. It was believed that a venesection might have done good, notwithstanding the patient died in a condition which was probably uræmic.

The interesting features in the case were:

First, the absence of all evidence, from examination of the urine, except the specific gravity, pointing toward chronic disease of the kidney. Dr. Robinson regarded this as not an infrequent occurrence, and he had already directed attention to the fact that a *persistent low specific gravity* of the urine was of great diagnostic importance, while the ordinary chemical and microscopical examinations of the urine—independent of the clinical history—would not permit the observer to say that kidney disease existed.

Second, the differential diagnosis between pneumonia and pleurisy, and also the absolute diagnosis of pleurisy. For a great many cases, the rule laid down in the text-books concerning flatness or percussion over the lower portion of the chest with diminution or complete loss of thoracic vibrations, was, according to Dr. Robinson's observations, inapplicable in the diagnosis of pleurisy.

Dr. Janeway said that some ten years ago he directed attention to the fact that vocal fremitus was not necessarily absent with pleuritic affections, and that pleuritic adhesions associated with consolidation of the lung on the right side seem especially favorable for the preservation of vocal fremitus. Some had held that there was some point in cases with adhesions, where vocal fremitus was retained, but that was not true of all cases. Moreover, he had seen cases in which, while the fluid was forming, vocal fremitus was retained. He had in some cases found vocal fremitus with purulent as well as serous effusion.

With regard to kidney lesions, it was sometimes very troublesome to make a satisfactory diagnosis. In some cases it was exceedingly difficult to find casts in the urine; besides, some patients will carry the small kidneys for several years, as many as nine, ten, and fifteen, as had already been done by patients still under his observation. The cases which gave most trouble in diagnosis were those of small kidney with urine of good specific gravity and not increased in quantity.

Dr. J. C. Peters referred to Skoda's writings as the most complete, with regard to pleuritic and pulmonary sounds and covering more disputed points, which he had ever read.

Dr. Seguin thought it would be well if microscopical examinations of urine, both in hospital and private practice, were conducted by experts. In hospitals such examinations were usually made by the members of the staff least qualified for such work, and besides, there was frequently insufficient time allowed to conduct them thoroughly.

Dr. Janeway referred to a case in which albumen appeared in the urine every time the patient took a sponge-bath, made any special mental effort, even the reading of a book, etc., and yet there had not been at any time casts, and the specific gravity had been good.

Dr. Waldstein referred to a family which, for three generations, had given albumen in the urine, but had been otherwise apparently perfectly well.

THE PRESIDENT presented a patient with

MALFORMATION OF THE FOREARM,

consisting of fusion of the radius and ulna. There was flexion and extension, but supination and pronation were absent.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CONCLUSION OF THE DEBATE ON PHTHISIS—DEGREES FOR MEDICAL MEN—THE UNIVERSITIES OF LONDON, OXFORD, AND CAMBRIDGE—THE NEW PROGRAMME OF THE UNIVERSITY OF VERMONT—MEDICAL OFFICERS OF HEALTH AND PRIVATE PRACTICE—CATHETERISM OF THE ŒSOPHAGUS—A NEW INSTRUMENT BY MR. SYMONDS—KRISHABER'S PLAN—SIR J. LISTER—DEATH OF DR. NOBLE.

LONDON, January 24, 1885.

THE discussion at the Medical and Chirurgical Society on the Pathology of Phthisis was concluded on Wednesday last, 21st inst.

The debate has been marked throughout by an unusual amount of unanimity of opinion compared with that expressed at most medical discussions. If, indeed, we are to take the opinions recently expressed as an index to the views held and taught now in our schools of medicine we may be said to be pretty generally agreed on the following points, viz., that phthisis is in all cases one and the same disease; that it is a specific disease marked in the great majority of cases by the presence of bacilli, and that in determining the nature of "tubercular" lesions their inoculability is a more reliable test than their histological characters.

At the resumption of the debate on Wednesday last, Dr. Sidney Coupland referred to the great contrast between present views and those expressed at the Pathological Society's debate twelve years ago. The term tubercle, then discountenanced, now appeared quite appropriate. Experimental inoculations used to be thought fallacious; now we thought histology insufficient to establish the nature of a tubercle. Applying this new test of bacillus to discriminate tubercular from other lesions, the field of tubercular disease is much widened. Koch found tubercle bacilli in cases of ulcers of the tongue, strumous pyelitis, chronic disease of the bladder and rectum, suprarenal disease, tubercular disease of the uterus, strumous disease of testis, in caseous tumors of brain, in caseating lymphatic glands, in granulation of chronic joint and bone diseases, and in lupus of the skin. These observations of Koch accorded with the accepted views of tuberculosis as a general infective disease which may attack the body at any point, and which is liable from thence to become further disseminated through the system.

Dr. Theodore Acland and Mr. Macnamara both referred to their failure to find bacilli in those tissues which had not been exposed to the atmosphere. Mr. Macnamara said that in five or six cases of tubercular disease in bone, thoroughly examined by him, he had never been able to discover the bacillus in the early stage of the disease, although he had often found bacilli when a sinus communicating with the open air led down to the diseased bone.

It is impossible to summarize the entire debate in the brief space at my disposal, for several speakers took part in the discussion besides those I have mentioned. I have, however, endeavored to epitomize some of the more important speeches. The debate concluded with a speech from Dr. Percy Kidd, who reviewed at some length the views brought forward by the various speakers. He said, in conclusion, that he did not think the bacillus afforded a complete solution of the tubercular process, though he believed it was essential.

I have several times referred to the obstacles encountered by London students in obtaining a "degree" in medicine. Considerable pressure is now being brought to bear upon the University to induce them to modify the more objectionable of their regulations. There appears to be some prospect of half-yearly instead of annual examinations, and it is rumored that the "logic and psychology," which has long formed such a stumbling-block to the M.D. examination, is to be finally thrown overboard. The failures in this subject at the recent examination have been extraordinarily numerous, and have brought the subject into odium in medical circles. I have heard of a candidate who was well up in medicine failing in logic three times in succession, and ultimately failing to get his M.D. at all, solely for that reason. The prospect of a new and more active University being founded will doubtless stimulate the Senate to institute some changes, though the unrepresentative character of that body and the large influence wielded by the permanent officials doubtless impede reform.

The opinion is growing daily that it is very desirable indeed that students of medicine should be enabled to obtain a *degree* on reasonable terms; that the possession of a degree should be the rule and not the exception for a medical man. Our metropolitan teachers feel very strongly on this point. We are, in fact, coming round to the American notion of one qualification for all, and that one to be M.D.

Under these circumstances it is satisfactory to find that the University of Oxford, which has been reproached for years as the "lost medical school," is awaking to its responsibilities. Dr. Sanderson was appointed Professor of Physiology a short time since, and at last a lecturer on human anatomy is about to be appointed. At Cambridge medical teaching is active, and the sum of thirty thousand pounds is about to be expended on new chemical laboratories.

The readers of the medical journals here have been somewhat startled to observe in *The Medical Times and Gazette* an advertisement from the University of Vermont, offering to confer the degree of M.D. (after examination, but without residence) on registered British medical practitioners. Without expressing any opinion as to the wisdom of this proceeding, I may just point out that by proper management it may be made a great success, and to the University of Vermont a financial success, if a good fee be charged. I observe they only ask six pounds at present. If the examination be a good one there is no reason why the degree should not get a good repute here.

LONDON, January 30, 1885.

The question of whether medical officers of health should be allowed to practise, is one which is exciting considerable attention. Those who would debar him from practice say, that he can the better perform the duties of his official appointment if he be not distracted by the cares of private practice. Other practitioners are also chary of reporting cases of infectious diseases to a health officer, who is also a rival in practice even in those towns where notification has been made compulsory. In obscure cases, when in doubt, the temptation is natural not to notify, not only because the medical officer of health may come in and contemptuously dispute their diagnosis, but because he may possibly get the patient for himself. On the other hand, such appointments, although they help to make a medical man known in the district where he lives, are not very direct recommendations to practice. Many families object to have a doctor who is popularly supposed to be always "smelling bad drains" and "seeing fever patients." The objection to forbidding the health officer to practise is chiefly the pecuniary difficulty. Few sanitary districts can afford to pay a salary adequate to secure the entire services of a suitable man. There are scores of rural districts where

the salary is only twenty pounds a year or less ; hundreds where it is under a hundred. This is gradually being altered by the creation of combined rural districts with one medical officer of health in charge, assisted by a competent staff of sanitary inspectors. But as yet only a beginning has been made in this direction.

At the last meeting of the Clinical Society Mr. C. J. Symonds exhibited a new form of œsophageal catheter, designed to be worn permanently in cases of stricture. It is of gum-elastic, about six inches in length, and resembles in construction an ordinary œsophageal catheter, except that at the upper end it expands into a funnel having an outside diameter of from one-half to three-fourths of an inch. The catheter is passed down to the stricture and the tube part is carried through it. The funnel rests on the upper border of the stricture and prevents the catheter from passing farther. A piece of silk, fastened to it, brought out at the mouth, and attached to one ear, serves to remove the catheter when required. Mr. Symonds showed a patient suffering from malignant stricture, who had worn one for six months. It was changed once a week at first, and afterward once in two or three weeks. He could swallow fluids freely and had gained in weight.

I believe the plan of retaining an œsophageal catheter permanently was first brought before the profession by the late M. Krishaber at the International Medical Congress, held here in 1881. His paper was read for him in English before the Surgical Section by Dr. Prosser James, the author having been unexpectedly compelled to return to Paris. The genial presence and linguistic powers of so distinguished a specialist as M. Krishaber will long be remembered by those who had the pleasure of meeting him in the section devoted to Throat Diseases. M. Krishaber showed that the best way was to pass a fine catheter by the nares, and although for a day or two it might produce some degree of rhinitis, tolerance was soon established and alimentation thereby assured. In one of his cases the tube was left in without changing for three hundred and five days, to the great comfort of the patient, who, however, ultimately died, his stricture being cancerous. Whether Mr. Symonds' method can compare with M. Krishaber's remains for future observation to decide.

Lister has received from the Emperor of Germany the *Ordre pour le Mérite.*

Dr. Daniel Noble, A.M., M.D., author of "The Human Mind" and other psychological works, died lately at the age of seventy-five.

THE TREATMENT OF DISEASES OF THE STOMACH BY THE LEUBE SYSTEM AT KISSINGEN.

To the Editor of The Medical Record.

Sir: During a recent trip to Europe, the writer had occasion to revisit Kissingen, after an absence of eight years. The place has not gained much in all that time, but neither has it lost any of its old-time attractiveness. In point of fact it continues to be one of the most popular spas in all Europe, the country par excellence of a multitude of popular spas. Among the vast throng of foreigners that annually flock to drink a certain number of goblets of delicious water in Kissingen, Americans occupy a prominent numerical position. And there can be no doubt that the pleasant little town affords unsurpassed opportunities for renewing any casual acquaintance one may have had with kings and queens and crowned heads generally. If you take a good orchestra seat at the theatre, for example, the chances are nine to one in your favor that you will sit next a queen or a duchess, either a reigning one, or one in exile, or one of the variety called ex. And should it be your misfortune to step on a person's toe without immediately begging his highness' pardon, you are very apt to get into trouble.

But the object of this letter is not to point out the great social advantages of a visit to Kissingen. The writer wishes to call attention to a new institute which has sprung up there within the past two years. It might not improperly be termed a gastric sanitarium, having for its sole object the rational treatment of the various forms of dyspepsia.

The founder and proprietor of this institute is Dr. Edgar v. Sohlern, and he explains in a pamphlet just issued [1] exactly what he has already done and what may still further be accomplished by strict regimen and diet, in conjunction with the judicious drinking of the Kissingen waters.

It is well known, according to Dr. v. Sohlern, that the number of persons suffering from gastric affections who seek relief from their ills by drinking the waters of Kissingen is very large. Yet they have not always derived the benefit that they might, owing to the lack of a proper supervision of their diet. In the treatment of gastric troubles a strict regulation of the diet is even more important than is the administration of medicinal agents, for if the weakened stomach be taxed beyond its powers by the reception of a mass of unsuitable food, its condition is simply aggravated, and any attempt to improve matters by drugs is but adding straws to the camel's back. Food which is easily digested by a healthy stomach may prove almost ruinous to one which is functionally or organically diseased, and hence the necessity for an intelligent supervision of the food prepared for dyspeptics, and for the regulation of their diet according to some definite system. It is evident, however, that no regimen can be successfully established and maintained unless the patients submitted to it be constantly under the eye of the physician. Patients with gastric troubles should no more be allowed to judge of their own condition and regulate their diet accordingly than should they or any other patients be allowed to choose their own medicines, or to decide upon the dose best suited to their condition.

This want of a proper institution for the rational treatment of gastric disorders has now been supplied by the author, who has opened a sanitarium into which patients are received and systematically treated, according to the method devised by Leube. By a series of experiments upon healthy people and those suffering from various gastric disorders, Dr. v. Sohlern determined the exact degree of digestibility of each of the ordinary articles of diet, and taking the results thus obtained, prepared bills of fare adapted to the actual and varying digestive capacities of different classes of patients.

The first diet list contains chiefly fluid materials, and is suited for the weakest stomachs. On account of the repugnance which many patients feel for liquid foods, a little variety is introduced by allowing cakes and *zwieback* prepared without sugar. For drink during this period simple water or water from the Maxbrunnen or other similar springs not too heavily charged with carbonic acid gas may be taken. After usually about ten days of this diet the patients are in condition to enter upon the enjoyment of the second bill of fare. Several kinds of solid food are included in this list, all of which are, however, boiled and not roasted or fried. In addition to simple soups, soft boiled or raw eggs, boiled brain, and boiled poultry without the skin are allowed. When the patient is able to use this diet without discomfort, he is advanced to the next grade. He is now permitted to eat raw ham and beefsteak, prepared according to Leube's method, also mashed potatoes, and small quantities of tea or coffee may be taken. At this time much benefit is derived from the use of the waters from some of the stronger springs. These hasten the digestive process and improve the appetite. Finally, in the last class, in which the diet approaches nearly to that of individuals in ordinary health, in addition to roast beef and some sorts of game, certain kinds of fish, white bread, vegetables

[1] Die Behandlung der Wagenkrankheiten nach Leube schem system. Von Dr. med. Edgar Frhr. von Sohlern. Kissingen, 1884.

and stewed fruits are allowed. For drink the patient may take a strong dry wine. This last bill of fare must be strictly adhered to for a considerable time, and any excess will be found to bring down a speedy punishment upon the offender. Not every dyspeptic is forced to advance through these four successive grades, the patient beginning in that class which is suited to his condition. The digestive capacity of the individual sufferer is determined by examination with the stomach-tube, and as soon as this is accurately ascertained he is put upon the appropriate diet, and is then advanced by degrees, in proportion as his stomach becomes stronger, until he is finally able to take ordinary food in normal quantities.

Frequent use is made of the stomach-tube, both as a diagnostic and as a therapeutic measure. Medicines are given but sparingly, and the waters are taken at proper times and in suitable quantity according to actual indications.

Leube's plan of treatment, as followed in Kissingen by Dr. v. Sohlern, he has found of great value in simple or nervous dyspepsia, acute and chronic gastric catarrh, and even ulcer of the stomach. It is also very serviceable in doubtful cases as a means of diagnosis between ulcer and carcinoma. For in the former case improvement quickly follows upon the establishment of a suitable regimen, while in cancer the progress of the disease is steadily from bad to worse, despite the most careful and systematic dietary treatment. There can be no doubt that a sanitarium, such as that of Dr. v. Sohlern, managed on physiological principles, assisted by rational empiricism, will supply a real want. Kissingen will be none the less popular for having an institute where more is thought of strict dietary supervision than any mysterious potency that may reside in a palatable water.

Yours, respectfully,
EDMUND C. WENDT, M.D.

THE KENSINGTON, 102 EAST FIFTY-SEVENTH STREET,
February 10, 1885.

AN EXPERIENCE WITH BOVINE VIRUS IN THE VACCINATION OF CHILDREN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your issue of January 3d contains an editorial on "The Injuries caused by Vaccination," in which the following expression is used, "Vaccination protects, and vaccination, if carefully performed, is safe."

I do not refer to it for the purpose of dissenting, for all physicians admit it in full force. Nor do I wish to extenuate in the least the objections or opposition of those pseudo-benefactors of the human race, who seek to depreciate the value of this, the most important sanitary measure known to medicine. It is rather to illustrate by the case cited below the difficulty of complying in all instances with the saving condition, "*if carefully performed*," in the above quotation that attention is directed to it.

On December 7th I received five points of fresh bovine lymph from the New England Vaccine Company. On the 8th my assistant vaccinated two infants (one five, the other eight months old), both apparently healthy and well. Both "took," so to speak, the first running through with the normal evolution of the vaccine vesicle; the other I was requested to visit on the thirteenth day (21st), and found a slough involving the entire thickness of the skin and cellular tissue beneath, about the size of a quarter-dollar, with abundant suppuration. The child had fever, with great restlessness, and the general appearance of one under septic influences. I felt apprehensive for its safety, but under antiseptic dressings and constitutional treatment it recovered.

Both children were vaccinated with virus from the same source, by the same person, and with similar instruments (ivory points charged with the lymph), and were alike healthy in appearance. Why the difference in the result? If the vaccine was at fault, like results should have been produced in both cases; if, however, the subjects differed in constitutional condition, the status of one contra-indicating vaccination, how could this be determined so as to comply with the terms of your precept, "if carefully performed?"

It would be a mere assumption to hold that a subtile constitutional condition perverted the vaccine and brought about septic results. This is insusceptible of proof, and if the healthy condition of a subject is made a precedent to safe and protective vaccination, judging from the case reported, it would be impossible to say in any given case that it could be done with safety. Whether the vaccine was at fault or not, vaccination furnished the occasion for the development of a septic state, although very carefully performed. Spurious vaccination (as this proved) affords no protection; hence, it must be done over, and with no greater security against a hurtful effect than at first.

I will add that when I used humanized virus exclusively I never saw such results, but since the introduction of bovine virus they have not been rare. I therefore distrust it, that obtained from the most approved propagators being alike amenable to the observation. Moreover, when humanized virus was alone within the reach of the profession here, control over, and protection against small-pox were as prompt and certain as at present, with fewer disasters entailed by vaccination itself. In the effort to escape transmissible disease from the human subject, it is feared that the risk of ordinary septic infection from virus vitiated by decomposing blood or lymph has been incurred, to the detriment of the claims of vaccination. There may be something too commercial in the management and direction of vaccine farms to keep the lymph furnished always within the limits of a *pure* vaccine. At any rate, with my present experience, I cannot believe that vaccine thus furnished to order, however convenient and popular it may be, is safer and more protective than that derived from selected subjects for humanized virus, as was formerly the case. The latter is open to abuse likewise; but the physician is directly responsible for what he gets as well as what he uses.

WILLIAM H. DOUGHTY, M.D.

AUGUSTA, GA., January 18, 1885.

A CASE ILLUSTRATING THE TREATMENT FOR OPIUM-POISONING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The following case, although it may not be instructive in a professional way, may be entertaining. "It is a true story." Among the students residing with Dr. H——, of Dublin, was a young man, who had received a very severe wound to his tender emotions in an *affaire du cœur*. One morning he was absent from the breakfast-table, and, as he had shown symptoms of "indisposition" for several days, a student was sent to his room to inquire into the matter. It was found that the young man had been taking laudanum, for a small bottle labelled tr. opii. and nearly emptied, was on the table by his bed, and deep sleep seemed to have overcome the victim of woman's treachery. Hastening down to Dr. H——, the student informed him of the dangeous condition of his medical brother upstairs. The doctor did not seem inclined to hasten, however, but, to the amazement of his scholars, went to a little closet and brought out a stout rawhide. Ordering a cup of coffee and some emetics, he proceeded to the chamber of the supposed suicide. The rawhide was concealed. A good emetic was administered, and afterward some strong coffee. "Gentlemen," said Dr. H——, "we have here a very interesting case of attempted poisoning with laudanum. The emetic, which I have administered, has happily proved successful, and the patient has received a cup of strong black coffee. He still remains in a drowsy, sleepy condition, and this, gentlemen, as you are well aware, is of

the greatest danger. Out of this sleepy state he *must* be brought, and he must be kept clear from it. I will remove the bedclothes." So saying the doctor pulled down the bedclothing, exposing the strong limbs of the youthful Æsculapius. *Whack* went the rawhide well across them at the same moment, skilfully applied by the patient's preceptor. Again the whip descended, and the poor student, smarting with pain, sprang from the bed and tried to escape. The strong arm of the doctor secured him, and the rawhide continued its cruel work. "Stop, in mercy, stop!" cried the miserable youth. "Gentlemen," said Dr. H——, "in cases of this kind it is your duty to keep the patient awake, and to endeavor to save his life. If you are hindered in your efforts by any false ideas of pity, of over-sympathy, you wrong your patient, and must be responsible for the consequences." Down came the cruel hide again, and, smarting with pain, the poor victim howled for mercy. "Gentlemen," exclaimed the doctor, "let this be a good lesson; never give up a case of opium-poisoning. As long as the patient is awake there is hope, and you must keep him awake." Again the hide descended and again, until at last the poor fellow protested that he had only swallowed a drop or two to make him sleepy, and that it was all pretence. "Gentlemen, never be influenced by the cunning of would-be suicides, who strive in every way to deceive, in order to make their dreadful attempts successful." Down came the hide again, and the poor sufferer began to think the misery would never cease. With a farewell cut the doctor let him creep into bed again. "Gentlemen, I think we can now leave our patient with safety to himself," and, turning to the sobbing student, he said: "If you ever really wish to terminate your life, which God forbid, go to some lonely place and do it, and keep your fellow-mortals free from the agonizing suspense."

William Thornton Parker, M.D.

Atlantic City, N. J., January 28, 1885.

A FULL REPORT OF THE GREAT NATIONAL CONGRESS OF SCIENTIFIC ANIMALS.

It happened that the beasts of the forest of Ouden, who were learned and skilful in relieving their fellow-creatures' pains, determined to have a General Congress for mutual talk.

They met at the time named and the Lion presided with great ease and dignity.

In making his opening speech the learned President said that theirs was a most noble profession.

He recounted the great progress which it had made, but believed that sanitary science was the thing in which the most glorious triumphs would be gotten. He touched upon the wonderful achievements of anæsthesia and vaccination, also upon Harvey and the circulation of the blood. He referred to Hippocrates, Galen, the immortality of the soul and the value of animal congresses, ending with a loud roar which was well received.

The Cinnamon Bear moved a vote of thanks for this unusually eloquent and profoundly original address.

Thereupon, business beginning, the Goose arose and moved that the Fox be expelled from the Assembly, as he had been seen consulting with the Duck, who was known to be no better than a Quack. This motion was immediately carried. The meeting then divided up into sections for the better study of the several scientific problems.

In the Section on Neurology, the Rabbit related the outcome of his special studies on the "Tendon Reflex in the Hind Extremities of Irritable Mules," and showed several flattened skulls to illustrate the effects and beauty of this phenomenon.

In the Section on Physiology, the Frog showed a beautiful instrument for registering in a graphic manner the movements of the kangaroo.

In the Section on Orthopedic Surgery, the Lamb read a paper of great originality upon the "Development of the Hump on the Camel," and showed an apparatus which, if worn constantly for seventeen years, relieved the deformity in a large number of cases. An earnest discussion began as to the real usefulness of this important invention, but it was promptly ruled out of order by the President.

In the Section on "Diseases of Women and Obstetrics," the Goat opened a debate upon the question Whether the Physician should support the Perineum, or the Perineum should support the Physician, which was well maintained.

Professor Guilielmus Capricornus read a paper contending that pessaries were a great national blessing and that all animals should wear them.

Professor Suis Ferus reported two thousand operations for sewing up the cervix uteri with fifteen successful results upon which he was warmly congratulated.

In the Section on Surgery the Ring-tailed Ape described his new operation for the treatment of intestinal wounds. This consisted in opening the abdomen, removing the whole abdominal contents, and substituting carbolized cotton, thus making the individual thoroughly aseptic.

The Sacred Ox of Burmah made a report upon plastic surgery. He described a case in which he had successfully attached the hide of a rhinoceros to the back of a horse, thus rendering a saddle unnecessary. He had also transplanted the skin of a hen to the head of the Bald-headed Eagle which had much relieved that animal from the effects of extreme heat and cold, and put a new face on the whole matter.

In the Section on Diseases of the Throat and Nose, the Elephant related a history of a patient with a hypertrophied proboscis in which the affected animal could twine the diseased member several times round his own tail—to make a long "story" short.

The Giraffe gave his experiences with sore-throat, which are too long to be reported here.

In the Section on Skin Diseases, the Rhinoceros reported the results of an analysis of one hundred and ninety-seven thousand cases of eczema treated by excision, each one having been treated in a different manner.

The Congress then adjourned to a Grand Banquet, and having visited the insane asylum, two shoe factories, and an orphan home, broke up to meet in the same place the next year.

General Grant at Shiloh.—In *The Century* for February, General Grant gives the following interesting account of a night's experience on the battlefield after his foot had been injured by the fall of his horse: "During the night rain fell in torrents, and our troops were exposed to the storm without shelter. I made my headquarters under a tree a few hundred yards back from the river bank. My ankle was so much swollen from the fall of my horse the Friday night preceding, and the bruise was so painful, that I could get no rest. The drenching rain would have precluded the possibility of sleep, without this additional cause. Some time after midnight, growing restive under the storm and the continuous pain, I moved back to the log-house on the bank. This had been taken as a hospital, and all night wounded men were being brought in, their wounds dressed, a leg or an arm amputated, as the case might require, and everything being done to save life or alleviate suffering. The sight was more unendurable than encountering the rebel fire, and I returned to my tree in the rain."

Acetate of Lead.—In acute œdema of the lungs acetate of lead may be given with decidedly good results in doses of 0.05, half hourly; more particularly in that form which occurs in the course of chronic nephritis, with general dropsy. But large blisters are used at the same time.

New Instruments.

THE FITCH CHLORINE BATTERY.

By I. N. GOFF, M.D.,
CAZENOVIA, N. Y.

At the recent meeting or the New York State Medical Society at Albany, I promised a number of physicians to furnish a short account of a battery cell made in this place by D. H. Fitch, and known as the Chlorine Battery. I have no interest in the matter, except to give to all interested just the information they require. The especial merits claimed for this battery, and which have been proved most fully, by practical use here, as well as in other places for the past five years, are its cheapness, the chemicals used being inexpensive and easily obtained of any druggist; its easy maintenance, as it requires no cleaning, and very little care, not being taken apart or changed when not in use, or at all moved when needing to be replenished, which does not often occur, and when necessary, costs very little; its freedom from fume or odor, which is caused by the absence of acids in its use; its durability and readiness for use; being free from corrosion and evaporation insures its durability, while it will not freeze in the lowest temperature known in this climate.

The Chlorine Battery is intended to be used more as a stationary than a portable one, thus it is adapted for office use.

A CONVENIENT HYPODERMIC SYRINGE.

Dr. A. Henri Hart, of this city, has devised a hypodermic syringe which greatly facilitates the use of tablets. The construction is very simple, and the instrument is not liable to get out of order. It is in appearance very like other double fenestrated syringes except that an orifice is made at the end, sufficiently large to admit any hypodermic tablet in the market. Ten, fifteen, or twenty minims of hot water (120° to 130° F.) are drawn in, the syringe inverted, the tablet dropped into the instrument, as shown in the cut, the needle screwed on, and the injection made immediately it dissolves. By the device, it will easily be seen, much time and trouble are saved, and the entire dose, as well as accuracy are assured. Compactness also is gained, for with this instrument four varieties of hypodermic medicine may be carried in the space formerly occupied by one vial of the usual solution of morphine.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 8, 1885, to February 14, 1885.

Town, F. L., Major and Surgeon. Granted leave of absence for twenty days. S. O. 14, Department of Texas, February 4, 1885.

February 14, 1885.....	0	5	16	4	28	32	0	

The Foods which do not Favor the Growth of the Comma Bacilli.—As the result of his studies in M. Cornil's laboratory, Dr. Babès finds that the comma bacillus will grow in milk, coffee, meat, carrots, leguminous vegetables, eggs, broth, but not in fresh or dried fruits, beer, wine, conserves, salted or smoked meat, or cheese.

Arsenic.—Cutaneous eruptions are said to be rare in parts of Sweden where arsenical limestone is present, and in Cornwall arsenical fumes, given off from copper-smelting works, are said to prevent ague from marshes in the vicinity. There is a river in Cumberland which is used for all purposes by the inhabitants, who enjoy particularly good health. Its waters contain a perceptible amount of arsenic. Arsenic is thought to be peculiarly valuable in skin diseases from nerve affections; also in chronic dyspepsia with diarrhœa of ill-digested food, and in intestinal mycosis. It is of the highest value in the distressing vomiting of drunkards, when one or two minims should be given before meals, so as to come in contact with the irritated membrane. In systemic affections it is best given after meals. In phthisis it is well known that it sometimes arrests the progress of the disease in a remarkable degree; when pain and fever are present aconite may be added.

A New Dressing for Wounds.—M. Marc Sée has invented a fresh dressing. He has tested it three times after excision of the breast, and speaks confidently of its success. When the operation is finished, the surface of the wound is powdered with bismuth, which arrests all oozing, and favors cicatrization; it is then covered with layers of cellulose impregnated with carbolic acid, upon which is placed a thick layer of cotton-wool; a tarlatan bandage is then placed upon it, and an india-rubber one is superposed. Before the dressing is completed, M. Sée places sutures, both deep and superficial, and drainage-tubes, which are easily removed by means of a thread which is attached to them.—*Brit. Med. Journal.*

RECENT RESEARCHES IN CHOLERA.[1]

BY EDMUND C. WENDT, M.D.,

NEW YORK.

THE recent European outbreak of Asiatic cholera has imparted the fresh excitement of a contemporaneous event to a disease, that may at all times profitably engage our attention. Add to this the further excitement inseparable from the authoritative announcement by Koch of his discovery of a special and distinct organism belonging to cholera, and it is not surprising that the medical press of all civilized countries fairly teems with articles, notices, theories, suggestions, and what not, concerning the dreaded pestilence. So bewildering is this mass of new literature that, at first sight, it seems impossible to decide whether we know anything, everything, or nothing about Asiatic cholera.

The object of my remarks is not the ambitious one of restoring order where hopeless confusion seems to reign. Nor have I a new theory to offer, that in the attempt to explain away all previous ones, will only make chaos a trifle more chaotic. I have imposed upon myself the humbler task of presenting a brief résumé of the present state of the cholera-question, as reflected by the light of the most recent researches.

There is substantial agreement on all sides that Asiatic cholera is emphatically an infectious disease of epidemic character. Its supposed germ or parasite has been discovered, forgotten, and rediscovered in some new shape many times. The latest doctrine, that advanced by Koch, does not materially differ, in theory, from many of the older views. A *contagium vivum* that, multiplying within the body of the patient, is responsible for the morbid phenomena of an attack, is the common assumption of all these views.

The reader then passed in brief review the opinions of Boehm, Britton, and Swayne, Snow, Budd, Pouchet, Davaine, Pacini, Farr, Kiehl, Ilisch, Pettenkofer, Thomé, Klob, Hallier, Macnamara, Lewis, and Cunningham, and finally gave a succinct account of Koch's doctrine.

Next he turned to the recent French investigations. Straus and Roux found comma-bacilli in choleraic stools, but attached no particular etiological or diagnostic importance to them. Magnon and Cognard experimented on animals with negative results.

The Marseilles Commission found Koch's commas, but do not accept his theory. Instead, they lay great stress on certain alterations seen in the blood-corpuscles of cholera patients. They also found that the blood has toxic properties in the algid stage, and that animals may take the cholera. They conclude their report by admitting that they have shown, "what cholera is not, rather than what it is."

Maurin and Lange describe a fungus which they call *mucor choleriferus*. It grows on the dejections, and leads at length to the secondary development of Koch's comma-bacilli. Their method is crude, their alleged discovery sterile. Rietsch and Nicati produced death in animals by introducing pure cultures of comma-bacilli into their intestines.

[1] Abstract of a paper read before the Medical Society of the County of New York, February 23, 1885.

The observations of Babes, fully confirmatory of Koch's views, those of Doyen, who found the comma-bacilli in various viscera and the blood, were then alluded to. Villiers and Pouchet declare that ptomaines are developed in the blood of cholera patients before death. Recent Italian and Spanish writers have made no important contributions to the cholera question.

The reader then sketched the controversy raised by Lewis, and Finkler and Prior, and indicated the nature of Koch's reply to his critics. He then took up Van Ermengen's earlier researches, which fully harmonized with Koch's results. The paper then proceeds as follows:

Still more recently Van Ermengem presented an important communication to the Belgian Academy of Medicine (*Bulletin de l'Acad. Royale de Méd. de Belgique*, vol. xviii., No. xii., 1884), on the inoculation of guinea-pigs with the products of comma-bacilli cultures.

The author begins by pointing out that, the transmissibility of cholera from man to the lower animals has been in turn affirmed and denied by many observers. In all epidemics, facts have been observed which were thought to point conclusively to cholera infection in dogs, cats, birds, etc.

Reputable authorities, such as Magendie, Meyer, Thiersch, Charcelay, Crocq, Legros and Goujon, Leyden, Burdon-Sanderson, Popoff, and others, have conducted experiments, the results of which seemed to them to be conclusive. But on the other hand the force of these positive results has been weakened by the negative conclusions of other experimenters, chief among whom are Schmidt, Guttmann and Baginski, Stokvis, Snellen, Högyes, Wolffhügel, and especially the commissioners of the English Sanitary Council in India. The unfailing want of success in the experiments recently undertaken for the same end by the members of the French and German missions in Egypt and Calcutta, respectively, has tended still further to establish the opinion that most of the lower animals are not susceptible to the action of the cholera poison.

In the face of these contradictory facts, it might be asked whether the choleraic symptoms sometimes observed were actually those of cholera. And this doubt is increased when the conditions of most of the experiments are more closely examined. Not only were the symptoms far from being always characteristic, but the lesions discovered post mortem were very diverse in character, and in many cases no autopsy was made at all. And besides, many sources of error, which have since been found to exist, were often not guarded against. Poisoning by ptomaines might explain many of the phenomena observed; and the experiments made some time ago by Stich have shown that the introduction into the circulation of excrementitious products contained in the urine or fæces may give rise to symptoms resembling greatly those of the algid stage of cholera. Then again, it required massive doses of the virulent material to produce tangible results, small doses, except possibly in the case of mice, having failed to excite alarming or fatal symptoms. Finally, facts were wanting to establish the poisonous nature of the dejections of the animals which were the subjects of experiment.

Thus it may be said that the experimental study of cholera, until very recently, was just where that of tuberculosis was prior to the memorable investigations of Villemin, Martin, and Koch. Pseudo-cholera has been produced by matters of the most varied kinds, but proo

is still wanting that the disease thus caused is specific in its nature and re-inoculable.

Van Ermengem had made a few attempts at inoculation in dogs without very definite results, when he learned of the experiments upon guinea-pigs conducted by Nicati and Rietsch. They seemed to him important as indicating that these rodents were, in an especial manner, susceptible to the action of the cholera poison, and he therefore turned his attention to them, using them in a series of searching and varied experiments.

The first experiments were made by injecting eight to fifteen drops (0.5 to 1.0 grm.) of a pure culture of comma-bacilli into the duodenum. Every one of the animals died presenting typical symptoms of malignant cholera, and the autopsy revealed lesions which completed the picture of the disease. Microscopical examination showed the presence of comma-bacilli in the contents of the intestine.

Several guinea-pigs were then submitted to an injection, in a similar manner, of a fraction of a drop of the culture fluid, the dose varying from $\frac{1}{5}$ to $\frac{1}{10}$ of a drop. Only one of the animals survived, and he presented some passing algid symptoms and had a diarrhœa for several days. His stools contained comma-bacilli nine days after the inoculation, which had been of about $\frac{1}{50}$ of a drop only of the culture fluid. All of the other animals died with choleraic symptoms, differing but little in intensity from those excited by the large doses. The lesions found post-mortem were those of cholera, and numbers of comma bacilli were found in the intestinal contents.

Another series of experiments was made to determine the virulence of intestinal matters taken from the animals subjected to the former inoculations. The subjects of these experiments died with choleraic symptoms, as did also other animals inoculated with their morbid products, the latter being, therefore, the third in the series.

Injections were now made with the products of cultures from which the bacilli had been removed by filtration, or had been killed by heating the culture to 140° F. or over for half an hour. In these experiments, when large doses were injected, the animals speedily succumbed with algid symptoms, but when small quantities were used no effects were produced.

To assure himself against error the author also examined microscopically the stools and the intestinal contents of healthy guinea-pigs. He sometimes found bacteria of a curved form and well-developed spirilli, but it was always easy to distinguish these from Koch's bacilli, for they were from two to four times larger than the latter, and differed from them also in their action in culture media. Similar forms were also found in the excrement of other animals and in impure water.

That the abdominal section required in order to make the duodenal injections was not the cause of the death of the animals, was shown by the recovery of several guinea-pigs subjected to the various experiments, for in them the wound healed readily without exciting any untoward complications. Several of those animals that recovered from the first operation were used a second time, and died with the usual choleraic symptoms. This would seem to show that one inoculation with the comma bacilli does not confer immunity.

Duodenal injections were also made of septic materials other than those containing comma bacilli, and in most cases were barren of result. In some few instances the animals died with symptoms of septicæmia, but never with those of cholera.

In reviewing the results of his various experiments the author maintained that they were sufficient to prove that cultures of the comma bacilli contain a very active toxic principle, which can only be the product of the vital activity of this microbe. This poison causes morbid phenomena and cadaveric lesions, differing but little from those of Asiatic cholera. He hoped to be able, with the assistance of a skilful chemist, to isolate this principle, and to compare it with that which Dr. Pouchet had recently succeeded in separating from the rice-water stools.[1] If these attempts were successful they might suffice to establish a very important similarity between the phenomena observed in experimental cholera and those which characterize the disease in man. In two autopsies of malignant cholera made by the author, there was such an absence of grave lesions that it was difficult to explain the fatal result by any changes in the intestines or other organs; the blood alone was profoundly altered. Similar discoveries have recently led Koch,[2] Straus and Roux,[3] and Klebs,[4] to admit that, in these cases, a powerful poison is produced in the intestine, to the absorption of which these grave constitutional symptoms and speedy death are to be attributed. The injection of filtered cultures, Van Ermengem stated, has caused in guinea-pigs a condition presenting the strongest resemblance to an attack of hyper-acute dry cholera.

Ceci and Klebs studied cholera at Genoa. In a preliminary report[5] the authors formulated twelve propositions, the pith of which amounts to the assertion that the commas and spirilli of Asiatic cholera looked precisely like those found by Prior and Finkler in cholera nostras.

Klebs also claimed to have discovered commas in the diarrhœal discharges of a patient having pneumonia.

In a more recent publication by Klebs,[6] he admits that a differential diagnosis between Asiatic and simple cholera is possible by the aid of Koch's comma bacillus. But he does not believe that it is always an easy matter to differentiate between the two. For the positive recognition of cholera spirilli he thinks the culture method is indispensable.

Dr. Gilbert Kirker, in an account of the Egyptian epidemic which paid a slight visit to Port Said (*British Medical Journal*, November 1, 1884) says: "That there is a particular microbe constantly associated with Asiatic cholera must now be admitted." To his mind, however, "it is not proved that the bacillus which has been found causes the disease."

Dr. Rudolf Emmerich was sent by the Bavarian Government to Naples for the purpose of studying Koch's comma bacillus in its relations to Asiatic cholera. An account of his observations was read at a recent meeting of the Medical Society of Munich (December 3, 1884). His material consisted of ten cases. In eight of these there was no difficulty in finding Koch's commas. In the remaining two they were missed.

But in addition to the comma bacilli, his glass-plate cultures showed colonies of another variety of microbe. Indeed, the latter sometimes preponderated over the comma colonies. Believing, however, that the mere discovery of a peculiar organism in the intestinal contents, and apparently nowhere else, could not sufficiently account for the disease, he decided to search elsewhere for their presence. He thought that the visceral lesions of cholera might, perhaps (reasoning from analogy with other infectious diseases), receive their explanation from the presence of cholera microbes within their substance.

Emmerich examined the blood and various organs of choleraic bodies by inoculating tubes containing sterilized solid culture media of various kinds. These tubes were then taken to Munich and their microbes studied by means of glass-plate cultures. In this way he discovered a new organism, held by him to be the true cholera microbes.

The same pathogenic organism he succeeded in cultivating from the blood of a young woman who was in the collapse stage of the disease, and died six hours after the blood was withdrawn from the median vein. He describes his method of procedure in the following manner:

The surface having been carefully washed with water,

[1] Compte rendu de l'Acad. des Sciences de Paris, No. 20, 1884.

[6] Ueber Cholera Asiatica. Basel, 1885.

alcohol. and a one per cent. solution of corrosive sublimate, the vein was punctured, and the blood, which was observed to be thick, trickled slowly out. The first drops, having been carefully got rid of, a previously heated platinum wire was passed into the vein, and on being withdrawn was then introduced into a test-tube containing solidified nutrient gelatine, and the latter was pricked in three places. Ten such tubes were inoculated in this manner, and it was afterward found that organisms developed in three of them. The remaining seven tubes continued to be sterile.

The organisms thus cultivated were always of one kind. They have a cylindrical form with rounded ends, and are found either singly or in pairs rarely with more than two segments. The length of each microbe is about one and a half times that of its width. According to Cohn's classification, therefore, they are bacteria, or better, short bacilli. As regards form and size they resemble those found in diphtheria, but are to be distinguished from the latter by the form of their colonies, when grown in gelatine and examined under a low power, and also by their action upon animals. They grow at ordinary temperatures in slightly alkaline gelatine as solid milk-glass-like patches. They do not liquefy the gelatine. Under a power of one hundred diameters such of the colonies as develop in the deeper portions of the nutrient gelatine on the glass plate, present the form of a millstone, and those on the surface simulate flat, circular mussel-shells. The deeper colonies look yellowish-brown by transmitted light, white by reflected light, and have a finely granular appearance. The more superficial colonies are pale-yellow toward the middle, and whitish at the margin. They manifest a tendency to spread over the surface as a thin transparent coating.

In cultures from the viscera they were found to be most numerous in the kidneys and liver, then in the lungs, and least numerous in the spleen. Emmerich ascertained that the greater number of the gelatine plates which were inoculated with the blood and with the juices of the several organs in cholera yielded, even in the first generation, a pure culture of this bacterium. The microbe has also been detected without resorting to cultivation in sections of the intestine and of the kidney. Other organs have not as yet been examined. Great numbers may be detected in the dejections and in the intestinal contents after death. They were found to grow in every gelatine-plate cultivation of choleraic alvine material, and in some cases occupied almost the entire surface of the plate; whereas in other cases, though more seldom, comma-shaped bacilli prevailed, but never to the exclusion of the particular organisms in question.

The results of some inoculation experiments, made at the Hygienic Institute of Munich, in conjunction with Dr. Sehlen, were also described. The animals experimented upon were for the most part guinea-pigs, and he believed that lesions had been induced in them by inoculation with this bacterium which closely resembled those observed in persons who had died of cholera, and especially as regarded the small intestine. The changes had been noticed to vary from a simple desquamative catarrh, with rice-water-like intestinal contents, to hemorrhagic exudation and ulcerative destruction of the mucous coat. A few drops of a solution prepared by the addition of a fragment of this bacterial cultivation to two or three drachms of distilled water, injected subcutaneously or into the lungs, gave rise to a protracted illness of from five to six days, accompanied with deep-seated changes in the intestinal mucous membrane. The injection of a larger fragment of the cultivation, covering an area of about a quarter of an inch, suspended in water, was followed by death in from sixteen to thirty hours, but with less marked pathological lesions in the intestine. The severity of the intestinal lesions being thus the more marked the more protracted the course of the disease, and the larger the dose the earlier the fatal termination.

The contents of the colon varied with the degree of the affection. It was either a flocculent whitish fluid, resembling rice-water, or more pappy, and in advanced cases mixed with blood. The mesenteric glands were found enlarged, the peritoneum congested, the cæcum and large intestine sometimes showed extensive ecchymoses. The spleen always looked normal.

These assertions of Emmerich were so direct and unequivocal that they created considerable stir in the medical world, especially in Germany. His methods and results were soon challenged, and he has not been able hitherto to substantiate more fully his claim to the discovery of a new specific cholera microbe.

Among others, Professor Flügge, of Göttingen, the well-known author of the standard treatise on the methods of hygienic investigation,[1] has published a refutation of Emmerich's positive claims. Flügge[2] states that Emmerich failed to obtain pure cultures. His alleged new cholera bacillus is merely a septic organism. The results obtained by inoculating animals, he could have induced equally well by using cadaveric products from any body not too long dead.

Emmerich's method of obtaining cultures could not stand the rigid test of scientific accuracy, which to-day is essential for experiments of this kind. Apart from all this, it was an error to assume that the cholera microbes must necessarily be present in the blood and viscera, in order to afford an adequate explanation of the symptoms of the disease.

The profound visceral changes observed in the bodies of choleraics belonged to protracted cases.

In typical acute cases rapidly terminating in death, marked histological lesions were found only in the intestines. Moreover, the number of cases examined by Emmerich was so small as to make any attempt at generalization seem *à priori* futile. This is the substance of Flügge's criticism, which, in turn, provoked a rejoinder from another source, namely, from a German observer, who, while claiming familiarity with Koch's methods, disclaims all partiality. This writer, a Dr. Buchner,[3] of Munich, is inclined to doubt the etiological importance attributed by Koch and others to the comma bacillus. He questions whether the microbes fulfil the conditions regarded by Koch himself as essential, before we can accept them as the true cause of a given disease. These conditions are "that the bacteria can be invariably detected in such numerical and local distribution as to fully explain the symptoms of the disease in question."

Buchner then proceeds to show that the comma bacillus falls short of this desideratum. But as regards the diagnostic significance of the comma bacillus, he asserts that there can no longer be any doubt. He alludes to the fact that all competent observers have found it. Koch saw it in Egypt, India, and France. Klebs and Ceci found it in Genoa; Van Ermengem saw it; Pfeiffer, Babes, and Emmerich observed it, and even Klein and Gibbes admit that they always found it. Every one of these investigators recognized it, according to Koch's description, not alone with the microscope, but by the various biological attributes shown in artificial cultures. The author thinks that indisputable credit is due Koch for having discovered by the aid of his excellent methods a parasite peculiar to Asiatic cholera, that must necessarily have some importance in connection with the pathology of the disease.

On the other hand, as regards the relation of the comma bacillus to the origin of an attack of cholera, Buchner states that we require further evidence before we can accept the conclusions even of a Koch.

In a pamphlet which has just appeared, Dr. A. Johne[4] asserts that the comma bacillus is the specific microbe of Asiatic cholera. Its discovery in the dejections of sus-

[1] Lehrbuch der hygienischen Untersuchungsmethoden. Von Dr. med. C. Flügge. Leipzig, 1881.

[3] Berliner Klinische Wochenschrift, February 2, and 9, 1885.
[4] Ueber die Koch'schen Reinculturen und die Cholera-bacillen. Leipzig, 1884.

pected cases renders diagnosis certain. He is also convinced that the culture-method of Koch can readily be carried out by the practising physician. In this way he asserts doubtful cases can be made certain in from twenty-four to forty-eight hours.

Dr. A. Pfeiffer,[1] during the recent outbreak of cholera in Paris, had occasion to observe twelve well-marked cases of the disease. The patients represented different ages, from two to sixty-two years, and both sexes. In two cases the attack terminated fatally within a few hours. One case of "foudroyant" cholera sicca was also observed. In six cases autopsies were performed.

In every one of these cases the comma bacilli were found either intra-vitam or post-mortem in the intestines. They invariably showed a decided preponderance over all other varieties of bacteria. In the three rapidly fatal cases the intestinal contents showed almost nothing besides the commas. In the intestinal glands of hardened specimens the bacilli were also seen by Pfeiffer. Dejections of patients afflicted with other diseases (pneumonia, measles, typhoid fever, phthisis), were examined, but no commas could be discovered.

Pfeiffer says that he also examined some swelled mesenteric glands of choleraics, but he found no commas in any of them. He says with reference to Emmerich's claims that he did not deem it necessary to search for comma bacilli in the viscera, because he thinks it incredible that in the large number of examinations made by Koch, that careful inquirer should have missed them. The Prior bacillus is, he holds, easily distinguishable from Koch's comma bacillus. Finally, he is convinced that the latter organism is the cause of cholera, and not a merely accidental occurrence. His reasons for this conviction do not differ from those of Koch for holding a similar belief.

At a recent meeting of the London Medical Society Dr. Heron demonstrated by means of specimens and cultures the differences between Finkler's microbes and Koch's commas.

The *British Medical Journal*, of January 17, 1885, in an editorial on the organisms of cholera, makes the following comment on this event: "It would, of course, be premature to form any decided opinion at the present moment, and especially before the results obtained by the English Cholera Commission are fully laid before us; but, so far as the published evidence goes, Koch would certainly appear to have established his point, so far as concerns the specific characters of the comma bacillus. It would appear that, in the controversy with regard to the comma bacillus, we have arrived at this stage. The bacillus described by Koch is always present in Asiatic cholera, though in varying quantities; it is also a distinct species, although numerous other species of bacilli, having the same form, may be found under a variety of circumstances. The precise nature of the causal relation, if any, between Koch's bacillus and cholera, remains to be ascertained. Dr. Koch, as we gathered from Dr. Heron's remarks, is quite satisfied that such a connection exists, and looks upon the bacillus as the cause of cholera. Few who have studied cholera Asiatica, from the point of view afforded by epidemiology, will be prepared to accept this statement in its entirety, and many will regret that Dr. Koch should have made a statement which, in spite of its apparent precision, is in reality ambiguous."

The editorial writer then continues as follows:

"There is one other reflection which cannot be avoided. Is it not almost a national disgrace that this country, whose responsibility with regard to cholera is so heavy, affords to investigators of this new aspect of the question so few opportunities of studying it? Is it satisfactory that a physician, who desires to acquaint himself with the present state of knowledge, should have to go to a foreign laboratory to obtain the necessary facilities? Is it creditable to us, as a nation, that living specimens of this much discussed bacillus should first be seen in this country under the conditions which we have mentioned—shown at an ordinary meeting of a society, and obtained, under a bond of secrecy, by the private enterprise of an individual physician? Such facts as these emphasize the justice of the demand for laboratories and appliances for the investigation of this and cognate subjects in England. Opportunities are required not only for carrying out original investigations, but for acquiring the skill in manipulation requisite for understanding and applying observations made for us already in other countries. This rich and powerful nation is falling behind its manifest duties. The story of the comma bacillus of Koch is only one out of many."

This does not sound far different from what I said concerning the United States in an article on cholera, published in THE MEDICAL RECORD of November 29, 1884.

In the *Deutsche Medicinische Wochenschrift*, January 15, 1885, Dr. R. Deneke, of the Göttingen Institute of Hygiene, reports the discovery in stale cheese of a species of curved bacilli. Subsequent careful investigations by approved methods brought out the interesting point that, morphologically as well as biologically, they resembled more closely the cholera bacilli of Koch than did the Finkler bacillus. It is not necessary here to give a detailed account of the points of resemblance and difference. The crucial test was made by inoculating guinea-pigs with pure cultures. In every instance the fluid to be tested was introduced into the duodenum of healthy guinea-pigs by means of a hypodermatic syringe. The animals remained in all respects well when the bacilli of Finkler and the cheese spirilli were injected, although about fifteen minims of culture fluid was used. The same quantity of liquid, containing, in one case, a single drop of culture fluid of genuine cholera, and, in a second case, only half a drop, was then injected in precisely the same manner as before. Both animals promptly died, and their intestines contained an abundance of cholera bacilli, showing that rapid multiplication had taken place.

The following brief summary of Deneke's conclusions may be read with interest:

"There is a group of spirilli, not widely disseminated, in which the younger individuals have a curved shape and show a tendency to form mature spirilli by juxtaposition. Several distinct kinds of spirilli belonging to this group are already known. A differentiation based merely on form is quite difficult, even with the aid of the best microscopes. With the aid of the culture method, a differentiation is much easier. Nutritive gelatine and potato constitute the best culture media for differential recognition."

Solid gelatine is fluidified slowly by Koch's cholera bacilli, much quicker by the cheese spirilli, and with greatest energy by the Finkler microbes. As regards potato, Finkler's microbes grow and spread readily, and at comparatively low temperatures. Koch's quite slowly and only at higher temperatures, Deneke's cheese spirilli not at all.

In experiments on animals the harmlessness of all but Koch's comma bacillus has already been alluded to.

Deneke asserts that Finkler's microbe has not the slightest relation to either simple or Asiatic cholera.

Dr. George Waters, writing to *The Lancet* (January 31, 1885), from Bombay, says that he found curved bacillli, identical in shape, size, and appearance with comma bacilli, in nearly all microscopic examinations of mucus from the small intestines of persons who had died from ordinary affections. He has also found identical organisms in neutral or slightly alkaline urine. In human urine he found curved bacilli within five minutes of its being voided from the bladder.

Nevertheless he regards them as an indubitable pathological feature of cholera, but more in the shape of a

[1] Ueber die Cholera in Paris. Deutsche Medicinische Wochenschrift, January 8, 1885.

consequence than a cause of the malady. Further on he believes the organism in question should be regarded more as a physiological than a pathogenic entity.

He concludes as follows: "If I say that a superabundance of comma-shaped bacilli is found in the small intestines of cholera victims, because it would appear that whatever gives rise to that ailment brings about exalted fermentation in that part of the alimentary canal, I shall, at least, have as much logic in my assertion as Koch had in declaring that these organisms must bear a causal relation to the disease."

Now, it is time that this kind of criticism ceased to receive the dignity of being printed in our leading medical journals. Waters makes no cultures, he merely sees something that looks like a curved bacillus, and immediately proclaims to the world that the results of months of arduous labor and cautious inquiry go for naught in the light of his puerile investigations. As a matter of fact, I have examined urine both in health and disease, both fresh and stale, and can assure you that I have discovered no bacteria in it that a good microscope cannot at once show to differ from Koch's commas. And, moreover, as has been pointed out again and again, even complete identity of size and shape would be far from proving identity in pathological potency or virulence.

Quite recently, at a meeting of the Royal Society, Dr. Klein[1] read a paper on the relation of bacteria to Asiatic cholera, embodying the results of an inquiry into the etiology of the disease, undertaken at the instance of the Government by himself, Dr. Gibbes, and Mr. Lingard.

The investigations of this English Cholera Commission have led to the following conclusions:

"1. Koch's statement as to the constant occurrence of comma bacilli in the rice-water stools of cholera patients is correct; the comma bacilli vary greatly in numbers in different stools and in different cases, in some being exceedingly scarce, in others numerous.

"2. These comma bacilli vary greatly in length, some being twice and three times as long as others, some well curved as much as to form half a circle, others showing only just a slight bend. The name comma bacillus is inappropriate; the organism is more correctly termed a vibrio.

"3. The comma bacilli occur in the mucus-flakes of the rice-water stools, as well as in those taken from the ileum of a person dead of cholera. The sooner after death the examination is made, the fewer comma bacilli are found in the mucus-flakes; even in typical rapidly fatal cases, the mucus-flakes taken from the ileum, and examined soon after death (from between fourteen minutes to an hour or an hour and a half), contain the comma bacilli only very sparingly indeed, and not to the exclusion of other bacteria. Our investigations do not bear out Koch's statement as to the lower part of the ileum being, in acute typical cases of cholera, almost 'a pure cultivation of comma bacilli.' In not one of the many post-mortem examinations of typical acute cases have we found such a state.

"4. The mucous membrane of the ileum, in typical rapidly fatal cases, if examined soon after death, does not contain in any part any trace of a comma bacillus or any other bacteria, not even in the superficial loosened epithelium. If the post-mortem examination be sufficiently delayed, comma bacilli and other bacteria may be found penetrating into the spaces of the mucous membrane. Koch's theory as to the comma bacilli present in the mucous membrane secreting a chemical poison inducing the disease cannot, therefore, be correct.

"5. Neither the blood nor any other tissue contains comma bacilli or any other micro-organisms of known character.

"6. The behavior of the comma bacilli in artificial media is not such as to justify their being considered as specific. They grow well in alkaline and neutral media, are not killed by acids, and their mode of growth in gelatine mixtures is not more peculiar than that of other putrefactive bacteria; they show marked differences when grown in different media, but not more so than the ordinary putrefactive bacteria when compared in their growth with one another. The comma bacillus of the mouth shows the same peculiar character of growth in gelatine as Koch's comma bacilli.

"7. Koch overlooked the fact that comma bacilli occur in other intestinal diseases, in the mouths of healthy persons, and, as shown recently, even in some common articles of food (by Dr. Deneke in stale cheese).

"8. The experiments performed by Koch and others on animals do not in the least prove that the comma bacilli are capable of producing cholera or any other disease. The results obtained by them are much more easily explained in an opposite manner.

"9. There is direct evidence to show that water contaminated with choleraic evacuations, and containing, of course, the comma bacilli, when used for domestic purposes, including drinking, by a large number of persons, did not, in the case of the tanks near the Jelepara Lane, produce cholera.

"10. The mucus-flakes taken from the small intestine of a typical rapidly fatal case of cholera, contain numerous mucus-corpuscles filled with peculiar minute straight bacilli; in this state they are found when the examination is made very soon after death; soon, however, the mucus-corpuscles swell up and disintegrate, and then their bacilli become free. The small bacilli are never mixed in the mucus-flakes. They are one-third or one-fourth the length of the comma bacilli, and about half their thickness. They are non-mobile; they grow well in Agar-Agar jelly, but show in their modes of growth no peculiarity by which they could be considered as specific. When grown on the free surface of the nourishing material they form spores.

"11. These small bacilli are not present in the blood, in the mucous membrane of the intestine, or in any other tissue.

"12. Experiments made with these small bacilli on animals produced no result.

"13. Since my return to London, I have ascertained that the comma bacilli of cholera show two distinct modes of division, one the known one of transverse division, and a second one of division in length. When growing in Agar-Agar jelly at the ordinary temperature of the room, after some days the bacilli swell up, owing to the appearance in their protoplasm of one or more vacuoles; as these vacuoles increase, so the comma bacilli become gradually changed, first into plano-convex, then into oblong bi-convex, and ultimately into circular corpuscles. The longer the original comma bacillus, the larger the final circle. These circular organisms are mobile, just as are the comma bacilli; and, by disintegration of the protoplasm at two opposite points, two perfect more or less semicircular comma bacilli are formed. Growing the comma bacilli in Agar-Agar jelly kept at higher temperatures (30 to 34° C.), the comma bacilli multiply by transverse division only; but, transferring these to Agar-Agar jelly, and keeping this at the ordinary temperature of the room, they again gradually change into circular organisms, which, by division in the diameter of the circle, form two new comma bacilli."

From an examination of these conclusions, it would appear that the English inquirers boldly take issue with every one of Koch's conclusions. The only item in which they are not in conflict with him consists in their admission of the constant association of comma bacilli with Asiatic cholera. But even this circumstance is not interpreted by the Englishmen in Koch's sense. Before passing final judgment upon the value of the British Commission's opinions, we will have to receive the full account of their labors. Their work seems to have been merely negative. New light is not shed upon the question by the results of their inquiries.

[1] British Medical Journal, February 7, 1885.

The following conclusions seem to me justifiable.

The detection of the cholera bacillus, even more so than that of tuberculosis, is so entirely dependent upon the skilled use of special technical methods, but recently elaborated, that we should be surprised that the discrepancies reported by different observers are not greater than is actually the case.

The concurrent testimony of a large number of writers of different nationalities is now sufficient to establish the rule that particular curved bacilli occur in Asiatic cholera.

Where positive observations are so numerous and harmonious, we may place a greater value upon them than the isolated negative evidences of a few experimenters.

As to the presence, then, in Asiatic cholera of Koch's comma bacillus, there can no longer be any question of fact.

Its relative preponderance in the lower portion of the ileum is still somewhat doubtful. And with regard to the various stages of an attack, and the differing gravity of separate cases, some of those most competent to speak from personal knowledge are not fully in accord with Koch, who finds the presence of the commas related to them in such a way that severity indicates, *cæteris paribus*, a preponderance of bacilli, and *vice versa*.

Nevertheless, by finding and proving the identity of these microbes by the culture method of Koch, we may have a diagnostic aid that should not be ignored. It may not be often that such additional assistance will be necessary, since the clinical signs of typical cholera are well marked and well known. But it is notorious that in the absence of an epidemic, such extra aid may become absolutely necessary to elucidate a particular case.

Koch's doctrine harmonizes so well with the clinical history of cholera that it ought to be accepted as the best theory yet offered in explanation of the disease. But it should be remembered that a theory is not a scientific fact. We need more evidence and renewed experimental observation before Koch's doctrine, in its entirety, can be made to permanently stand or hopelessly fall. Many observations point to the possibility, mentioned by Koch, of the comma-bacilli producing ptomaines or similarly virulent products of vital action in the bodies of their hosts.

The great credit belonging to Koch consists in the fact that he has pointed out to us the paths along which future inquiry must go. We are to-day able, thanks to his excellent technique, to pursue bacteriological researches with much greater accuracy and definiteness than was possible even a few years ago. As with tuberculosis, Koch's discovery of a distinct organism has given us clearer views, so it is likely to be with cholera.

It is true, we have not yet been able to ascertain the full truth. Future views and conceptions concerning the intimate nature of cholera may vary as much as past ones have done. But when the history of cholera shall be written, fifty years hence, it will have to be stated that Koch's discovery of the comma-bacillus constituted a decided step in advance in the pursuit of scientific truth.

Bitter Almonds contain an albuminoid substance called emulsin; and in addition one or two per cent. of a white, crystallizable nitrogenous substance called amygdalin. Now if emulsin is brought in contact with amygdalin, in the presence of cold water, the emulsin acts as a ferment, and, without undergoing a change itself, causes the amygdalin to split up into the essential oil of bitter almonds and prussic acid, and causes poisoning. If amygdalin is first injected into the blood of animals, and one hour afterward emulsin is sent after it, death speedily ensues; but not if the experiment is reversed.

Ammonia. — The liquor ammoniæ anisatus of the Germans should be used more largely than it is in flatulence and pyrosis, in the second stages of bronchitis or pneumonia, and in many states of debility.

ÆSTHESIOMETRY.[1]

By GRACE PECKHAM, M.D.,

RESIDENT PHYSICIAN TO THE NEW YORK INFIRMARY FOR WOMEN AND CHILDREN

ÆSTHESIOMETRY is the title, in default of a better, which has been given to the few considerations which I would present with reference to methods of examining the cutaneous sensory apparatus.

In the investigation of cutaneous sensibility the following classification is usually employed: I. General or common sensation, including pleasurable and unpleasurable sensations. II. Tactile sensation, which includes the sense of temperature, of pressure, and of locality.

I. General or Common Sensation is tested by pricking, pinching, tickling, or, best of all, because most accurate and because one is able to determine by it the amount of time requisite for a sensation to reach the nerve-centres, the faradic current.

II. Tactile Sensibility.—1. *Sense of pressure.*—Several instruments have been invented to record the power of the individual to determine mere pressure.

Weber's is the simplest. It consists of a rod, with a disk of wood, as a non-conducting substance, to place flat upon the surface of the skin. The weights are arranged with a hole through the centre, so that they can be strung upon the rod.

Dohrn's instrument consists of a non-conducting disk arranged on a spring, so that upward pressure is recorded on a scale.

Eulenberg's paræsthesiometer is a spring balance with a dial to record varying pressure. He has found, in observations with this instrument, that a differential pressure of one-thirtieth to one-fourtieth of an inch can be discriminated by the skin of the face, one-twentieth to one-tenth of an inch by the skin of the hand, arm, and anterior aspect of the thigh, leg, and dorsum of the foot.

Goltz' instrument, an india-rubber tube filled with water, whose waves in rising and falling record the smallest variation possible, is the most accurate.

It is interesting to find that the scale of pressure-results corresponds very accurately with those of Weber for sense of locality, with the exception of the tip of the tongue, which stands much lower.

It should be remembered that a colder weight is felt to be heavier than a warmer one, and that the sensitiveness is greater for an increase than for a decrease of the difference in weights, and also greater for a small absolute pressure than for a large absolute pressure.

2. *Sense of temperature.*—Numerous are the devices for determining temperature, varying from the simple methods of plunging the extremities into hot and cold water, blowing on the skin at a distance to test sensation of cold and breathing upon it to test that of warmth, the using, as did Weber, of test-tubes of oil heated to a known degree, to the complicated thermæsthesiometers of Eulenberg and Nothnagel, both of whom made the most delicate experiments possible. Nothnagel has shown that the small variation of 2° F. can be distinguished in the most sensitive portions of the body and 4° F. in the least sensitive.

3. *Sense of locality.*—This, of the various manifestations of sensibility, is the most commonly tested, and for this purpose Sieveking invented the æsthesiometer. Observations, as is well known, are based upon the physiological fact that two tactile impressions at certain distances, these distances, variable in different parts of the body, become fused into one. Sieveking's æsthesiometer was made with one point fixed, the other movable upon a bar upon which is a scale. Weber used a pair of compasses. Other æsthesiometers have been modifications of these two ideas. Dr. E. C. Seguin modified Sieveking's by making it of lighter metal. Dr. W. R. Birdsall has somewhat changed the same model, he has added a concealed needle for testing sensibility to pain,

[1] Read before the New York Neurological Society, January 6, 1885.

and has arranged it so that it can serve as an electrode, which has greatly added to its value, as it changes the instrument from one simply testing locality to one which can be employed in tests for common sensation as well.

Dr. W. A. Hammond has an instrument of the compass variety, which goes by his name at the instrument dealers.

The peculiarity of the æsthesiometer invented by Dr. Carroll is that the legs of the compasses are bifurcated, thereby providing two sets of points, one blunt, the other sharp.

Dr. Burq's æsthesiometer, which is also on the pattern of a pair of compasses, provides for this in a different manner. The sharp points are encased within ivory tubes, so that the points can be screwed back and forth like the lead in a pencil.

During a year of testing with the æsthesiometer, while making a careful study of the subject of metallotherapy, I was often led to notice the difference made in the quickness of perception by varying simultaneously the pressure of the two points. It occurred to me that an unconscious variation of pressure might easily mislead the investigator. An æsthesiometer which, without being clumsy, would record pressure, would be a desirable instrument. The æsthesiometer after the Sieveking pattern is, I think, more easily managed than that modelled upon the compasses. I therefore had one made like Dr. Birdsall's, which is on this principle. It is light, has a

concealed needle, and can be attached to an electrode when the screw at the end is removed. Mine differs only from his in that the points are attached to spiral springs which allow of upward pressure. These springs are attached to a small rod, which is divided into degrees, each of which represents a pressure of 30 grms.

The instrument might also be used to test simple pressure by adjusting to one of the points a disk of non-conducting substance, as wood. To test roughly the sense of temperature, two disks might be fixed to the two points, one of wood and one of metal.

A slight degree of pressure, almost unconscious, records thirty or sixty grammes, and yet it makes a great difference, often narrowing what the Germans call the sensation or tactile diameter one-third or one-half. The extent to which pressure increases the power of discrimination varies in different parts of the body. It is much less where the sensibility is most acute, as at the finger-tips.

By way of illustration simply of æsthesiometric variations with and without pressure, the following two cases are given.

In Case I., that of a young man, an ordinary æsthesiometer showed no difference between the two sides of his face, but he had a feeling of numbness in the left.

	Right Side.[1]	Left Side.
Forehead, (24 mm.)	−P. 8 mm. 5 mm. + 2° P.	Forehead, − P. 8 mm. 5 mm. + 2° P. Answer less prompt.
Cheek,	−5 P. mm.	Cheek, − P. 7 mm.
(11.25)	4 to 5 mm. + ½° P.	Same + ½° P.
Chin,	5 mm. + P. or − P.	Chin, − P. 8 mm. 6 mm. + 1° P
Neck, (33.75 mm.)	5 mm. + P. or − P.	Neck, − P. 7 mm. 5 mm. + 1° P.

This case shows that the slight difference between the two sides without careful regard to pressure would be lost.

[1] − P. denotes use of æsthesiometer without pressure, + P. use of pressure 1° = 30 grms. The figures in parentheses show the distances given in Weber's tables as normal for the parts.

Case II.—Woman who complained of left leg, with constantly increasing inability to use it in walking. Diminished faradic excitability in both nerve and muscle.

Right Side.		Left Side.	
Thigh, (77.5 mm.)	− P. 35 mm. 10 mm. + 2° P.	Thigh,	− P. 35 mm. to 45 mm. 15 mm. + 1° P.
Anterior of leg, (40.5)	− P. 40 mm. 29 + 1° P.	Anterior of leg,	− P. 40 mm. 20 mm. + 1° P. (Marked hesitation.)

In order to make more accurate observations with the æsthesiometer, therefore, the following suggestions are made :

1. The same pressure should be used for corresponding parts which are compared or tested ; if variations take place they should be recorded. It has already been indicated how easily an anæsthesia which was present might be masked by the varying pressure unconsciously used.

2. When comparing parts, the points of the æsthesiometer should be used in the same direction, that is either longitudinally or transversely, remembering that in the latter case the tactile diameter is smaller than in the former, a distinction made by Wundt, who says that Weber's *empfindung-kreise*, or circles of sensibility, should not be circles, but ovals. Nevertheless, Weber recognized the fact, and gives as exception the tips of finger and tongue.

3. The response may vary, so Ross says, with the direction in which the points of the æsthesiometer are approached or separated ; they are appreciated at less distance when commencing with the points wide apart and then having them approach one another.

4. Both points should be applied simultaneously, and with equal pressure.

5. One part should not be tested too long. The patient soon becomes weary of answering, and indifferent in his responses. Moreover, the attention really becomes fatigued. Again, if the tests are made too rapidly, the sensations, like those of the other special senses, become confused.

6. The nature of the response demands consideration, whether it is prompt or hesitating. If the latter, whether the slowness is due to a natural inability to respond quickly to external stimulus, or whether it depends on the presence of an abnormal state. It must be remembered, too, that the centres can be educated, so that improvement noted from time to time may be due to this.

7. The patient, of course, should not look, nor should the instrument be used according to the preconceived notion of the patients. As illustrative of this, I recall an instance of a lady, who having watched while I tested the sensibility of a friend, at which time I had happened to use continually two points of the instrument, invariably answered "two" when her turn came to be tested, though one point was used more often than two. This was not a case of retained impression, though I have met with such. One woman would answer "three" and "four," especially if pressure was used, instead of one and two. Brown-Séquard cites several cases of this kind where there was hyperæsthesia, due to injury of the crura and the pons. Wundt also has remarked it in cases of lesions of the spinal cord and in patients who had received small doses of strychnine. In such cases, he says, it is easy for the patient to mingle a subjective feeling with one from without. In my patients there was no organic trouble demonstrable. It is easy to account for it as due to retention of impressions, as happens in the other special senses, especially in vision, when it takes some time for an object firmly impressed on the retina to become effaced. Kottenkamp and Ullrich have found that after persistent experimentation normal

individuals feel two points constantly instead of one. I have also observed this.

One of the most important considerations in connection with the subject is, what should be considered the normal distance at which the two perceptions become distinguishable. The table most often quoted is that of Weber. Vierordt has confirmed it, as have, after careful experimentation, Kottenkamp, Ullrich,, Paulus, Riecker, and Hartmann. Sieveking and Valentin have also given scales. The distances by Valentin are much less than those of Weber. As a general thing I have found them less than either. The cases which I have already presented to show difference of pressure will indicate this, and they are typical.

The matter is rather *comparative* than definite. I think it is practically so considered, but too little stress has been placed on this by writers on the subject. Wide variations occur, because of environment. To judge from Weber's tables, which have been substantiated by the experimenters who have been named, the Germans must have less of the *raum* or *ort-sinn* than Americans or those who have resided in this country for a number of years.

Goltz and Czermak have stated that the touch diameter is much less for children than adults, such whose intelligence could be relied on to answer. It is probably because the skin is more delicate. For this same reason there would be variations between men and women, between those whose skin was protected and those whose skin was not.

It is therefore a matter of comparison between corresponding parts of the same individual, rather than between individual and individual, hence the importance, in order to obtain correct results, of making the tests of these corresponding points exactly alike as far as possible, by placing the points in the same manner, and in regulating the pressure.

DIABETES MELLITUS.[1]

Diet versus Drugs in its Treatment.

By G. C. SMYTHE, A.M., M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS, INDIANAPOLIS, IND.

It is a favorite amusement with some physicians to discuss *most* subjects about which they know the *least*. This is not the reason, however, which I shall assign for calling your attention to diabetes mellitus, although my ignorance of some branches of the subject will be sufficiently apparent before I am through with the discussion. I have nothing new to offer in the way of causes, no new symptoms, no new tests for sugar, do not intend to attempt to explain the pathology of the disease, or engage in the discussion of the controversy between Claude Bernard and his followers, and Pavey and his disciples, in regard to the glycogenetic functions of the liver. It is not necessary to assent to, nor dissent from, the nervous origin of the disease, with its implied vaso-motor paralysis. For my present purpose it is simply necessary to know —and that is all that is really known about the pathology of the disease—that it is impossible for a diabetic to oxidize or assimilate starchy or saccharine food. The border line is so closely drawn between physiology and pathology that no man has as yet been able to put his finger upon the broken cog in the machinery.

The question, then, which I wish to introduce for discussion is, whether the facts recently developed in the treatment of diabetes by the proper regulation of the diet, etc., do not warrant us in modifying the prognosis of the disease and making it more favorable?

Cantani, Flint, and others have claimed in recent publications that certain cases are curable; that the lives of all, or nearly all, cases may be prolonged. While I am not prepared to say from my limited experience that the disease can be permanently cured, I do believe that, when taken in time, the lives of diabetics may be indefinitely prolonged, and that they may be made useful and happy citizens. I wish to report a few cases, with some closing remarks.

Case I.—C. J. K——, aged sixty-nine, consulted me August 16, 1882. Had always been an active business man, engaged in mercantile and manufacturing enterprises. Within the last few years had met with some reverses, losing a large amount of property by fire at one time, and again by bad faith and unfair dealings of a partner. This patient has always been what is denominated a good feeder; does not remember the time when he did not have a good appetite, and says he has always been a great water-drinker, especially after supper. For the last three months has been steadily emaciating, losing during that time about twenty-five pounds in weight; feels weak, and is exhausted by slight exertion; does not pass a large quantity of urine, probably about eighty ounces per day; but finding no other symptoms present in his case sufficient to account for the progressive emaciation, I decided to examine his urine. Specific gravity 1.040, with an abundance of sugar.

He was placed upon a strictly nitrogenous diet, and his urine carefully examined daily until the eleventh day, when all traces of sugar had disappeared. No medicines were prescribed, excepting alkaline mineral waters to correct constipation. He was furnished with the necessary means to test his own urine, and directed to try certain other articles of diet. He finds that in addition to the nitrogeneous articles already permitted he can use various fruits and berries, together with some vegetables.

The patient continued to improve, no sugar appearing in the urine, only occasionally from errors in diet, until about six months ago I directed him to take a solution of bromide of arsenic, which he has taken at irregular intervals, since which time he has eaten sparingly of starchy food without sugar reappearing in the urine. He has been eating about half-a-dozen ordinary water-crackers, made from white flour, at each meal recently with no bad effects. I have kept careful watch over the patient, frequently testing his urine and finding it free from sugar. He is in the enjoyment of vigorous health for a man of his age, and still has full charge of his business.

Case II.—I. S——, aged fifty-eight, farmer by occupation, consulted me January 18, 1881. Has been emaciating for several months, much more rapidly recently; loss in weight to this date is about forty pounds. Passes two gallons of urine each twenty-four hours. The specific gravity of the sample examined was 1.045, with an abundance of sugar. Has all the other symptoms of diabetes mellitus. Says he has been suffering in this way, although not so badly, for about twelve years. Patient was placed upon the nitrogenous diet, and after the bowels were thoroughly acted upon by saline cathartics, he was put upon a treatment consisting of opium and ergot. On January 25th the amount of urine had diminished to about one-half, with a specific gravity of 1.032; sugar much dimished. It was again tested upon February 9th, when all traces of sugar had disappeared and the quantity diminished to sixty ounces per day, with a specific gravity of 1.015. Patient was instructed how to test his urine, and directed to enlarge his diet. I have examined his urine frequently since, and have always found it free from sugar. His improvement was rapid, and seems to be permanent. He is in vigorous health, superintends his farm, and also performs a large amount of manual labor. He has taken no medicine for several years, excepting an occasional dose of calomel, which he claims relieves him of constipation better than any other remedy. He now eats all kinds of fruits and berries, many vegetables not on the bill of fare, and partakes freely of bread made from the

[1] Read before the Putnam County Medical Society, Greencastle, Ind., January 13, 1885.

so-called gluten flours, which are usually composed of more than fifty per cent. of starch.

Case III.—S. C——, aged forty-two, consulted me February 20, 1879. Had lost thirty pounds in weight in the three preceding months; had always been a hearty eater, partaking freely of saccharine and starchy food; always drank water freely, and supposed it natural to pass large quantities of urine; does not remember the time when he could pass the night without urinating once, and sometimes twice during the hours usually devoted to sleep. The amount passed in twenty-four hours at the time he consulted me was two gallons; specific gravity, 1.028, with an abundance of sugar; had used two barrels, at twelve dollars each, of that greatest of all humbugs, Bethesda water, before consulting me.

When informed of the nature of the disease from which he was suffering, he absolutely refused to take any medicine, but promised to faithfully conform to the prescribed diet.

He was furnished with the necessary means to test his urine, and began the treatment at once. In ten days he called again, when his urine was diminished to two quarts, with a specific gravity of 1.010, and entirely free from sugar.

The nitrogeneous diet agreed with the patient; he soon regained his lost flesh, and continued cheerful and happy for about two years, when he began to clamor for bread, and, as his urine had been entirely free from sugar for nearly two years, I procured for him several specimens of the so-called gluten flours.

Sugar made its appearance promptly in the urine after the use of these flours. The patient continued, however, to use bread made from them sparingly for nearly two years without any marked symptoms appearing, such as thirst, increased appetite, or emaciation, or even a greatly increased flow of urine, yet sugar in small quantities was always present. For the last six months he has returned to the nitrogenous food strictly, or only eating such fruits and vegetables as careful testing has shown to be harmless, and, to all appearance, has recovered his old-time vigor. His urine is little, if any, above the normal in quantity; specific gravity varies from 1.015 to 1.020, and is entirely free from sugar. He is attending to all his business, and is capable of performing a large amount of labor, either physical or mental. I regard this case as of peculiar interest, because he took no medicine, yet his improvement was as rapid and as satisfactory as those who took drugs.

Case IV.—Miss K. M. N——, aged twenty, by occupation a teacher, consulted me January 18, 1884. She had lost forty pounds in weight during the nine months preceding. Passed over two gallons of urine in twenty-four hours; specific gravity 1.055, containing a large quantity of sugar; great thirst, insatiable appetite, etc. Had great muscular weakness, indisposition to perform any kind of labor, either mental or physical; had gloomy forebodings on account of having lost a brother with the same disease a short time previously; had not menstruated for four months.

She was placed upon an absolutely nitrogenous diet for a few days, and given to drink freely of alkaline mineral waters (Carlsbad), sufficient to produce free catharsis. By thus eliminating all undigested starchy materials remaining in the bowels, and depleting the volume of fluid contained in the blood-vessels, the sugar deposited in the tissues will be more readily absorbed and eliminated from the body. In five days the quantity of urine was diminished more than one-half, it was free from sugar, and the specific gravity had fallen to 1.015. Her diet was carefully enlarged and her urine tested every few days. She regained her lost flesh, began to menstruate in March, and resumed her occupation as a teacher a few weeks later. Several months since, I prescribed bromide of arsenic in her case. After taking it a few days she ate some white bread, which was followed promptly by a reappearance of the sugar. She remains in vigorous health, but has been unable to partake of starchy or saccharine food.

Case V.—R. K. H——, aged sixty-five, farmer and trader by occupation, consulted me August 2, 1884. Had lost about thirty pounds in weight during the last few weeks; had been suffering greatly from thirst, craving appetite, etc. This patient was passing one and one-half gallon of urine each twenty-four hours. The specimen examined by me had a specific gravity of 1.038, and was highly saccharine in character. He had been a heavy consumer of starchy and saccharine food, such as white bread, potatoes, rice, syrup, etc.

He adopted the prescribed diet readily when warned of his danger, and being a man of intelligence he was furnished with the necessary chemicals to examine his urine and taught their uses. In about ten days his urine was free from sugar; specific gravity 1.015, and quantity diminished to less than sixty ounces. Thirst and appetite normal. Sleeps all night without a call to urinate. His bowels were purged with alkaline mineral waters, after which he took a solution of bromide of arsenic after each meal for two or three months. I have tested his urine frequently and have found it free from sugar, although he uses bread in moderate quantity. This is an apparent cure. How much the arsenical preparation influenced the result I am unable to decide.

Case VI.—Was called to see upon the same day, and in the same house, although no relation to Case V., M. S. T——, aged fifty-seven, farmer by occupation. Had been suffering from diabetes for about two years, and had been treated by several physicians, and taken different medicines without benefit. Had not been upon a restricted diet. He was emaciated and feeble; weight, formerly one hundred and seventy-five pounds, reduced now to one hundred and seventeen pounds. Patient had been suffering for two or three days from an attack of acute indigestion, and had taken little or no nourishment during that time, and in consequence the amount of urine, together with the specific gravity of the same, had been greatly reduced. The specimen which I examined showed an abundance of sugar, and had a specific gravity of 1.028. No influence which I could bring to bear upon this patient could induce him to submit to a strictly nitrogenous diet for more than two or three days at a time. Notwithstanding this, there was some improvement in his case, and he gained seven pounds in weight; but he finally broke away from all restraint, and indulged freely and frequently in starchy and saccharine food, and died with diabetic coma December 23, 1884.

In reporting these cases, in order to economize time and space, all minor details have been omitted. It should be thoroughly impressed upon the mind of the practitioner that every case of diabetes is to be studied and treated by itself. Different cases vary widely in their causes, symptoms, and pathology. The progress already made by the disease when we are consulted, the age of the patient, etc., will materially influence the prognosis and treatment.

Before the age of puberty little can be done to stay the progress of the complaint. If the disease has progressed so far that the sugar cannot be eliminated from the urine in the course of ten or twelve days by simply regulating the diet, a cure is not to be thought of. To prolong the life of the patient under these circumstances for a few months is the best that can be hoped for.

The first thing which should be done is to free the patient's urine from sugar. This can be done in favorable cases in a few days by placing the patient upon a strictly nitrogenous diet, aided, if necessary, by evacuants such as the alkaline mineral waters. Nothing is more grateful to the stomach of the diabetic than a copious draught of Carlsbad water, and no restriction should be placed upon him in regard to the amount of fluid taken; his thirst will subside as soon as the sugar is eliminated. Water can do him no harm, but a withdrawal may result disastrously. With the disappearance of sugar from the

urine all the disagreeable symptoms subside—thirst, frequent and copious urination, etc. With a good supply of nitrogenous food, such as the patient can oxidize and assimilate, the craving appetite is also disposed of. If this condition of affairs can be brought about, our prognosis is correspondingly favorable, and while I am somewhat doubtful about being able to produce permanent cures, I do believe that the life of a diabetic, under favorable conditions, can be prolonged indefinitely by proper management.

Having freed the patient's urine from sugar, we are then prepared to study his individual case. It is a matter of surprise to note the difference in the ability of different patients suffering from this disease to assimilate foods of different kinds. Some can use starchy food in small quantities without sugar appearing in the urine; others cannot use the smallest quantity of starch, but can assimilate small quantities of cane-sugar; others can use all kinds of fruits and berries without detriment, while others cannot. Again, many patients can use milk and sugar, and consequently can use milk in all their foods where it can be used for cooking, etc., while a small quantity in others will cause sugar to appear promptly in a few hours after its ingestion; others can partake rather freely of certain vegetables like cabbage, tomatoes, and onions, while others cannot, and so on. These are some of the reasons why I insist that each case of diabetes must be studied and treated by itself. Every article of food which can be added to the list of a patient suffering from this disease is a great gain for him, and contributes very much to his happiness.

The time which elapses after partaking of food in these experiments, and that at which the urine for examination is passed is of the greatest importance. Sugar makes its appearance in the urine in a few minutes after the ingestion of starchy or saccharine food, and if a single indulgence is permitted, all traces of it will have disappeared in six or eight hours, so that a patient may eat these forbidden articles at the morning or noon meal, and no sugar appear in the night's urine. In order, then, to decide whether any given article of food is permissible, the first urine passed after the indulgence should be tested for sugar. In this way every article of food about which there is any doubt should be carefully verified in each and every case of this disease.

It is absolutely necessary that the diet of the patient at first should be restricted to the so-called meat diet, including meats of all kinds, fresh or salted—beef, mutton, pork, bacon, tripe, tongue, sausage, game of all kinds, poultry; fish of all kinds, fresh and salted; oysters, lobsters, crabs; eggs cooked in any way; butter, cheese, and all oils and fats. Almost every case of diabetes, especially if seen sufficiently early, can assimilate the articles mentioned above, or a sufficient number of them, to furnish him nourishment. He can drink without detriment tea, coffee, and buttermilk.

There are other articles quite numerous which are debatable; some patients can use them without prejudice freely, while others cannot. These articles should be carefully tested after the sugar has been eliminated from the urine as before suggested. This list comprises cream, curds, sweet milk, and many vegetables, such as lettuce, endive, spinach, cabbage, cauliflower, coleslaw, broccoli, string-beans, watercress, celery, asparagus, turnip-tops, young onions, cucumbers, pickles, olives, tomatoes, etc. While a majority of diabetics can eat these articles, or most of them in moderation, occasionally a patient will be found who cannot, and the only way to decide the question is to carefully test the urine for sugar after their ingestion. Most patients can use as food certain nuts, as almonds, walnuts, butternuts, filberts, pecans, Brazil nuts, but neither peanuts nor chestnuts.

There is a great difference in the power of patients to appropriate fruits; some can eat apples, peaches, and pears with impunity, others cannot use any of these; blackberries, raspberries, and strawberries without sugar, can be used freely by most patients suffering from this disease. I have one patient who can eat all the above-mentioned fruits and berries, but cannot use oranges or bananas. He can use apples grown in this latitude, but cannot use those grown in Michigan or New York. There seems to be a difference in the kind or amount of sugar contained in these Northern products which the patient is unable to oxidize.

It would seem that the bill of fare heretofore given from which to make selections of food would be amply sufficient to satisfy an ordinary mortal. But such is not the case. The one article not enumerated in this list, and for which they all clamor sooner or later, is bread, and I am sorry to say that no substitute which is at all satisfactory has been discovered.

In my younger days I experimented, very much to the detriment of my patients, with the so-called gluten flours of different manufacturers. No preparation of this article that I have examined contained less than fifty per cent. of starch, and many samples contained more starch than the whole wheat flour ordinarily contains. I want to caution the younger members of the profession to avoid the errors I have made. While some of these preparations are doubtless wholesome and nutritious foods, they are utterly unfit for diabetics, and while I have not tried the almond bread recommended by Pavy, I am satisfied that it will prove to be hard to digest, unsatisfying, and unsatisfactory as a substitute for bread with this class of unfortunate patients. Even the bran flour made by the Compton process is not free from starch, small traces of sugar appearing in the urine of some of my patients after its use; it is a poor substitute for bread, one of its chief advantages being that it enables the patient to eat butter freely by furnishing something upon which to spread it. It is better that all attempts to furnish bread should be abandoned. The appetite for it should be crushed out. It requires great firmness upon the part of the physician, and great will-power upon the part of the patient to do it. Yet I have a patient who has not tasted bread for six years, and yet he says he can do without it with less trouble than he can quit the use of tobacco. Bread is the one rock upon which diabetics are wrecked. All other articles of diet are readily surrendered.

Patients should be impressed with the fact that their lives are in their own hands, that medicine in the present state of our knowledge is powerless to cure them, but that they can prolong their own lives indefinitely if they do not partake of food which they cannot appropriate. It should be impressed upon their minds that the more starch and sugar they eat the hungrier and thirstier they become. In ages gone by saccharine and amylaceous foods were not used to the extent that they are now, they are modern inventions so to speak. Primeval man perhaps subsisted largely upon animal diet, with fruits and berries. His ability to oxidize starch and sugar has been brought about by the slow process of evolution. Every living thing subsists upon its own appropriate food. We are all creatures of environment. The ox would fare badly upon raw meat, while the lion would starve upon fodder. The diabetic has his own appropriate food, upon which he can subsist and be a happy and useful citizen.

The object of writing this paper was to call particular attention to the importance of diet in treating this disease, and to claim that all the benefits heretofore achieved in the management of this complaint have been by the proper regulation of the same, and that medicines are of no use whatever in controlling the diabetic process, and that they should be used as adjuvants only. Of course the functions of all the organs should be regulated by medical treatment when necessary, the same as in any other disease.

In addition to the regulation of the diet other hygienic treatment is of great importance. These patients contract cold easily. Their temperature is nearly always below the normal, usually as much as one degree, and sometimes more. The normal temperature of a diabetic

is in the neighborhood of 97° Fahr. This, perhaps, is owing to the imperfect oxidation of food. The respiration of this class of unfortunates is abnormally slow. I have noticed in all my patients that respiration is seldom more frequent than 14 per minute, and in some of my patients as slow as 12 per minute. From this fact it will be observed that diabetics receive at least twenty-five per cent. less oxygen than the normal individual. The question presents itself right here, Could he oxidize saccharine and starchy food if he received the normal quantity of the gas? Taking cold is simply abstraction of heat carried beyond the point of healthy reaction. This is one of the chief dangers of the diabetic, and should be carefully guarded against. It causes catarrhal inflammations which may result in unabsorbed pneumonic deposits in the lung, which undergo cheesy degeneration with a destruction of the lung and death from phthisis pulmonalis. Warm flannels should be worn at all seasons of the year, and where the patient can afford it, the winters should be spent in a warm climate, or, what is better, permanent residence should be taken in a warm, equitable clime. The most serious objection to the last suggestion is that Southern climes do not generally abound in wholesome, nitrogenous food. The skin should be kept in good condition. Too much bathing should not be indulged in, either hot or cold; both methods abstract heat unduly, and should be used with great care by diabetics.

It is unnecessary to give a complete list of articles of food which cannot be used by the sufferers from this disease. Any article containing sugar or starch in appreciable quantities must not be used, such as bread, either white or brown, excepting the bran bread made by the Compton process, and that sparingly, no potatoes, rice, or preparation from the Indian corn, etc. In fact, nothing but the articles mentioned as proper previously should be used.

The highest specific gravity which I met was 1.060; the lowest, which contained appreciable quantities of sugar, was 1.008. Sugar appears in small quantities without raising the specific gravity to any considerable degree in testing certain articles of food, after the urine has been freed from this substance.

I have been asked what effect was noticed upon the disposition of my patients which could be properly assigned to the influence of nitrogenous diet. I think they are more active and energetic. They lose the drowsy, heavy, stupid habit of the heavy starch and sugar consumer. They possess a more irritable temper than heretofore, partly owing to the diet and partly to the disease. Case III., who has eaten nothing scarcely but animal food and berries and fruits for six years is entirely different. He was indolent and lazy, he said, all his life until he began the treatment. He is now very active, possesses a ferocious temper, and makes everything about him keep moving. Yet I cannot detect a trace of disease about him. He eats well, sleeps well, and is free from aches and pains of all kinds. Starchy food in the diabetic holds the sexual functions in abeyance, but a strict adherence to the nitrogenous diet for a short time fully restores them.

The effect of a nitrogenous diet is soonest noticed for its effect upon vision, especially upon the presbyopic. Some of my patients were using spectacles for this anomaly at an early age; soon after beginning the treatment they were enabled to lay aside their glasses.

This led me to experiment with other patients who were presbyopic, but who had not diabetes, and were afflicted with paroxysms of sick-headache and other maladies. In every case experimented upon there was great improvement in the vision. Other points of interest present themselves to my mind, but I have already exceeded the limits allowed by our by-laws and must defer the matter for the present.

January, 1885.

THE COMMA BACILLUS.—A Koch sure thing.

REPORT OF A CASE OF ATROPINE-POISONING.

By H. P. LOOMIS, M.D.,

LATE HOUSE-PHYSICIAN TO BELLEVUE HOSPITAL.

Miss X——, an intelligent and refined woman, twenty-eight years of age, who had been educated as a trained nurse, while convalescing from a mild attack of continued fever, was ordered a solution of the sulphate of atropine for the relief of profuse night-sweats. The solution ordered was intended to contain $\frac{1}{100}$ of a grain of the salt to each drachm. Through mistake in compounding, each drachm of the solution contained one grain of the sulphate of atropine. This amount was taken at 10 P.M. The patient at once remarked the peculiar taste of the medicine, and knowing its nature feared that an overdose had been taken. I was immediately summoned, and reached her ten minutes after the drug was taken.

Two minutes after swallowing the poison there was a sense of burning and dryness in the throat, which rapidly increased; in ten minutes the voice became husky, the face deathly pale, and the pupils slightly dilated. At this time I administered a mixture of tannin and animal charcoal, and seven drops of the fluid extract of calabar bean. At 10.15 P.M. the patient was very restless, talkative, and slightly delirious. The face presented a peculiarly wild maniacal expression, with marked protrusion of the eyeballs. The early pallor gave place to a livid redness, which extended over the neck and chest, presenting the appearance of a diffuse erythema. The pulse, which half an hour before the drug was taken was 72 per minute, had increased to 150, and was soft and compressible in character. The nurse in attendance had administered ♏ xij. of Magendie's solution of morphine hypodermically, and ℥ vj. of whiskey by the mouth. The notes taken at the bedside are as follows:

10.25 P.M.—Respirations, 30 per minute; pupils are extremely dilated and do not contract under strong light. The patient moves her eyes incessantly from side to side, tosses about in bed, and keeps up a constant incoherent talking. About ℥ ss. whiskey is given by the mouth.

10.30 P.M.—Pulse, 162, small and thready; respirations, 35; delirium violent; aphagia is marked. Whiskey ℥ j. was now given hypodermically.

10.45 P.M.—Pulse increased to 170; respirations, 60 per minute and shallow. The delirium has become so violent as to require restraint, and is accompanied by choreaic movements of the limbs. There is intense hyperæsthesia, most marked in the optic and auditory nerves, less so in the cutaneous. ♏ xij. of Magendie's solution of morphine and ℥ iss. of whiskey were administered hypodermically.

11. P.M.—Patient is sleeping quietly, but starts at the slightest noise. Pulse, 154; respirations, 30; temperature, 98½°; surface hot and dry; no change in the pupils. ♏ xl. of whiskey have been administered hypodermically as often as the pulse and general condition indicated.

12 P.M.—For the past twenty minutes patient has been sleeping heavily, but easily aroused; lies motionless, with great muscular relaxation and partially closed eyes. The cutaneous hyperæsthesia has given place to marked anæsthesia, so that there is no pain on introduction of the hypodermic needle. Pulse, 150, and small; respirations, 20. ♏ viij. of Magendie's solution of morphine have been given hypodermically. Patient seen by Professors A. A. Smith and Janeway, who advised stimulation by aqua ammoniæ, to be given hypodermically. The continuation of the morphine in quantities sufficient to control the delirium was also recommended. The question of giving jaborandi was considered, but owing to the feebleness of the heart it was not deemed advisable to administer it, because of its well-known action as a cardiac depressant.

6 A.M.—During the night fits of violent delirium coming on suddenly have alternated with periods of pro-

found stupor. Pulse is now 130, although during most of the night it ranged above 150; respirations are 16. Attempts have been made to pass the catheter, but owing to the urethritis and vaginitis, accompanied by a swollen condition of the parts, it is found impossible to enter the bladder. At each attempt the patient became so violent that cardiac failure seemed imminent, therefore it was deemed advisable to desist from further efforts to empty the bladder for the present. Dilatation of the pupils has slightly diminished. Hypodermics of whiskey have been given during the night according to indications, and morphine, hypodermically, in divided doses, to the extent of twenty-four minims.

10 A.M.—Patient awake, but only partially conscious. Complains of great soreness in her throat and numbness in the extremities. Pulse, 128; respirations, 16; temperature, 100⅘°. Catheter passed with difficulty, and ten ounces of a dark-colored urine drawn. From this time the patient continued slowly to improve, but was not entirely rational until twenty-seven hours after the poison had been taken, at which time she is very restless and wakeful, constantly talking, with periods of mild delirium. An acute inflammation of the whole intestinal tract followed. The inflammation of the urethra and vagina subsided on the fifth day. The mydriasis continued for twelve days, accompanied by slight focal disturbance. For weeks the peculiar effect of the poison upon the nervous system was evidenced by great nervousness and irritability, a constant loquacity, forgetfulness of names and events, inability to use words correctly, and a wakefulness which could only be overcome by the use of opiates.

All the urine excreted—from the time of taking the poison until the end of the second day—has been chemically examined by Mr. Charles Rice, Ph.D., Chemist of the Department of Public Charities and Correction, who prepared extracts of the urine by means of benzine and chloroform, the concentrated aqueous solution of which proved, by physiological trial, the presence of a mydriatic alkaloid. Chemical analysis fully established the presence of atropine, the quantity of which, approximately estimated by Mayer's test, amounted to 0.054 gramme, or about three-fourths of a grain.

The following points seem to me to be of special interest in this case:

First.—The large amount of atropine taken. I can find but one recorded case,[1] in English or American journals, in which so large a quantity of the salt was taken and recovery occurred.

Second.—The primary retardation of the cardiac pulsations, which is stated by many observers to be of constant occurrence, was not noted, although the patient was seen within ten minutes after the ingestion of the poison, and before its paralyzing effects on the vaso motor centres was evinced by dilatation of the capillaries.

Third.—The elimination of the atropine. By chemical analysis over three-fourths of a grain of atropine was recovered from the urine secreted during the first forty-eight hours after the ingestion of the poison. It is evident that by far the larger portion, if not all, of the salt was eliminated by the kidneys.

Fourth.—Effects on the intestinal tract. The drug produced almost complete exfoliation of the intestinal mucous membrane, a result of atropine-poisoning I do not find mentioned. Perfect casts of portions of the intestines were passed for a number of days, and it was near the close of the second week before a movement of the bowels would not cause excruciating pain.

Fifth.—The evident antidotal effects of morphine. Within the first hour and a half over one grain of morphine was given hypodermically, followed by unquestioned beneficial results. The pulse became slower, the respirations were decreased, and the patient passed from a state of wild delirium into one of comparative quiet. It was not until nearly one grain of morphine had been given, however, that its full effects were obtained. Its antagonistic action was plainly seen in the rapidity with which the controlling power of the opium passed away and the entire absence of any symptoms of narcotism. At no time during the first night was there a longer period between the hypodermic injections than two hours, and within the first seven hours nearly two grains of morphine were given without producing the least impression upon the pupil. Upon the patient's general condition, however, the result was most marked and salutary. It seems to me that the bold use of opium saved the life of the patient, the best index to its administration being the delirium. About fifteen minutes alter taking the poison seven drops of the fluid extract of calabar bean were given, but as it was administered in connection with large doses of morphine, it is impossible to formulate any definite statement in regard to its effects.

Sixth.—The peculiar after-effects of the poison upon the nervous system. The centres which preside over speech seemed to be principally affected. The patient talked incessantly to those about her, always in a perfectly rational manner, however. Her attendants found it impossible to keep her quiet, and she herself appreciated the condition and remarked her inability to refrain from expressing verbally every thought which passed through her mind. Naturally of an amiable disposition, she became peevish, dictatorial, and very excitable. During convalescence the patient was troubled with neuralgic pains, most severe along the course of the nerves of the lower extremities.

The peculiar action of the atropine upon the secretions was most markedly shown in the condition of the synovial membranes and tendon sheaths. As soon as the patient left her bed there was considerable stiffness in and about the joints, which by the end of the second week had so increased as to almost prevent motion after a night's rest. It was only after repeated efforts and gradual limbering of the muscles that the patient was able to walk. The joints could be heard to creak, and a friction fremitus, on rubbing the tendons, was readily appreciable.

54 East Thirty-fourth Street.

GARLIC AND RABIES—A HISTORICAL REVIEW.

By J. L. CONTE, M.D.,

Deerfield, Ind.

The London *Standard* had, not long ago, an article entitled "A Remedy which is Infallible for the Cure of Rabies." In the beginning a very little attention was given to this discovery, but ever since the above referred method has been used with good result, the *new* discovery is spoken of everywhere. The Bouley system is the following: "The wound is first washed with water, then it is covered with pulverized garlic, and in addition, for eight or ten days the patient must take a strong decoction of garlic, and for a longer period use food prepared with garlic." I will not here argue the preventive, or curative merits of this *discovery;* but what is disgusting me is, to see how medical men will accept this agent (garlic in *rabies*) as a *new* discovery of Bouley, as a *new* method of Bouley, when all this we can read in the writings of authors who lived before our Lord Jesus Christ.

It seems impossible to me that there should be among the faculty such want of knowledge of ancient medicine; it seems that all that has been observed and written by the ancient physicians is looked upon as a dream, a romance, a chimera!!!

In our days students think that the bread of medical science can only be found in the richly bound volumes, with clear types and printed on beautiful paper; the sight

of snuff-colored, dusty, half-Latin and half-Greek volumes gives them the sea-sickness.

The present scholar thinks that these old books and their theories are dead as the authors; they look for new theories in new books—new! new! It is a question of taste; for my part I rather prefer these veteran books, the reading of which had with me always a peculiar result, viz., to demonstrate that the *new* books are *old*, and to prove that a great many *new* discoveries are very *ancient*. And this is illustrated in this Bouley discovery, Bouley specific, Bouley treatment. And here is what I have read with my own eyes.

1. Paul of Egina, a renowned Greek physician who lived 420 years before Christ, in his work "De Re Medica," edition of 1542, published by James Guinterius, from page 198 to page 201, first speaks of means to protect the human family from the sting of venomous animals, and says that it is necessary to close their "cavas latebras allio in aqua detrita;" that if any one should be bit by some poisonous animal, and the poison had made its way into the blood, then it is necessary to bleed at once and feed the patient food well prepared with pepper et *allio;* and when afterward he specifically speaks of "De Rabbiosi Canis Morsus," after a magnificent description of the symptoms of *rabies canina*, he speaks of its curability, among other remedies he advises "Vel ulcera (the bite) prius formentis adiuta *allio* oblinis. Then he speaks of cataplasm on the bite of a mad dog, and after advising cataplasma of *cepæ* (onions) cum sale et ruta, advises also that of *allio*, and speaking of draught says, "potio idem efficiunt *allio* porri cepæ in cibo sumpta."

2. Dioscorides Pedacio, Greek doctor, born at Anazarbe, in Cilicia, a military medical man of great renown under Julius Cæsar and friend of Marc Antony and Cleopatra, born fifty-six years before Jesus Christ, author of a treatise on materia medica and of a work entitled "De virulentis Animalibus, et venenis, cane rabioso eorum notes, ac remediis, libri quatuor," in the first work of five books, at page 71 of second volume published by De Sabio Nicolinis Venetiis, 1538, chapter 49, *De allio*, says: "*Allio* contra rabiosorum morsus et ellitu (ointment) et cibo valet."

3. Petrus De Abano, born at Vico Albano, near Padua, in 1250, a celebrated astrologer, doctor, known by the nickname of "Conciliator," and who died while under indictment in 1316, in his "Libellus Sane Aureus," etc. (De Venenis, nunc postremo recognitus suæque, etc.) Venetiis apud Joa Gryphium, 1550, a very rare edition, which by the way is the second edition, the first having been published in 1537, at page 50, chapter xiii., says "De Morsu Canis." After describing first the symptoms presented by the rabid dog, and afterward the symptoms presented by the bitten man, speaks of the treatment and says: "Quod ejus cura est, ut super locum morsus ponatur ventosæ cum scarificatione et ponantur Desuper Allium sive cepe tritum, et confectum cum butyrum, vaccino et sumat in potu electuarium cancrorum fluviatium (crabs).

4. Santes De Ardoynis, of Pesarus, a distinguished doctor in medicine who lived in 1430, under the Emperor Sigismondus, in his "Opus Venenis," printed in Venice by Octavious Scotum in 1492, plainly stated that "Allium Agrimonia Oxyapathum," are remedies useful against the bite of mad dogs, and says that these substances are useful because "sunt quæ per vias urinæ de corpore eliminant" (the rabid poison).

5. Salius Diversus Petrus, a learned physician and philosopher of Faenza, in his treatise "De Febre Pestilente" edited in 1583, speaking also in regard of "curationes quorundum particularium morbosum" in p. 333, edition published by A. Wechely, of Frankfort, in the year 1581, very elaborately and scientifically speaks of the "morsus canis rabiosi" and of its treatment and curability, and in regard of the curability, after having stated that if the patient (as it was the usage) refused to be burned, says: "Applicatur emplastrum a Dioscoride desumptum. Quo frequenter usus sum cum felicissimo successu in pauperibus et corporibus durioribus et in his etiam qui chirurgicam manum non admittunt ex *allio cepos* et granis tritici commansis compositum." And the author, after having stated that this treatment is also a part of prevention, so much so that the author never heard or saw any one afflicted with rabies if "eius ulcus recta cum ractione fuerit pertractatum," then passes to indicate the internal treatment and which food can "venenum refrangere et quæ idem ad viscera penetrare proibeat," and that these articles are, "vinum potens et dulce radices acriores, ut *Allium cepos porrum raphanus*, etc., et potus sit copiosus." And in reading the splendid article of Diversus, we cannot fail to notice how he warmly recommends the use of white hellebore in powder and in draught mixed with *allio* in rabies.

6. Vicus of John, from Trapallus, a surgeon who lived in the sixteenth century, in his work of "Practice." in the seventh volume bearing for title "De Natura Simplicium," p. 584 of the Lugduni apud Honoratum edition, 1587, speaking of the medical properties of garlic, wrote: "Allium—similiter etiam decoctum et pistatum cum noce et ficubus ac theryaca omnibus venenosorum animalium morsuris intus et extra administratum magna est medicina.

7. Andrea Cesalpini, a renowned philosopher, naturalist, and physician, in his "Praxis universæ artis medicæ" (Venetiis, 1680). at p. 247, chapter xxxv., in indicating the treatment of the bite of a rabid dog first says, "Eductio virus ex vulnere," and afterward, if the wound made by the bite is not closed, "imponendum *allium* sylo detritum," and internally does repeat the advice of Dioscorides, viz., use "*allium cepæ porra*, quia vix (the power of the poison) abolentur."

8. Richard Mead, born in London in 1673, illustrious writer on toxicology, in his valuable work "Mechanica Expositio Venenorum," published in 1737, republished his famous thesis written in 1735, "De Cane Rabido," in which he is recording and analyzing with minute observation the ancient remedies, and among others the *allium* as the remedy which when used internally, "per vias urinæ de corpore eliminat" the rabid poison. He also, like Dr. Cornelius Celsus, warmly recommended "Curatio omnium maxima et tutissima, submersio in aqua frequens.

I could go beyond the seventeenth century, but it would take too much paper and time; but if you want to satisfy your curiosity, read the work of Andry, "Recherches sur la rage," 1777, and Portal, "Observations sur la nature et sur le traitement de la rage," of 1779, and you will be satisfied that that of Mr. Bouley is *not a new discovery*, as the press states.

I shall close by asserting that the statement of Mr. Bouley's discovery of the medicinal property of garlic in hydrophobia is an *unpardonable blunder* in medical literature; it is a mistake in the medical history, because it is beyond doubt that the use of garlic as local and internal treatment, and as preventive against the rabid virus in the human organism, is a remedy known more than four hundred and twenty years before the birth of Christ, and this is beyond doubt. This new invention is another charlatanism; another crow clothed with the dazzling feathers of the peacock! For shame! Such unblushing effrontery is an insult to the medical fraternity, which should be exposed and not let go by unnoticed.

THE ORIGIN OF CHOLERA EPIDEMICS.—Dr. John H. Rauch calls our attention to the fact that he does not forget the history of cholera elsewhere than in the United States, but has distinctly stated that "Cholera is a capricious disease, and the history of its various pandemic extensions throughout the Old World affords occasional instances of a single introduction sufficing to inaugurate an epidemic."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 28, 1885.

THE CIVIL SERVICE EXAMINATION.

IN accordance with the laws of the State, in the future, all public medical positions will have to be obtained by competitive examination. This is but part of the general plan of removing from political favoritism and trade the incumbents of public office. That this scheme is admirable nearly every one not directly interested in politics will concede; and particularly in medical positions that directly involve considerations of health and life, a plan of selecting capable and faithful men is urgently required. But exactly the best method for selecting the best man does not seem to be so plain. After escaping the ward politician, the unhappy applicant may find himself under the dreary tyranny of the cram quiz. In other words, examinations may be so conducted as not practically to test a man's fitness for a medical office, but rather his ability to quickly absorb vast masses of theoretical knowledge. In such a contest a man of affairs, who could bring to an office the practical knowledge derived from years of experience, has no chance beside the recent graduate or the parrot-like glibness of the quiz man. We do not in any way wish to underrate the great value of the theoretical groundwork of medicine. All success must be based upon a solid foundation of anatomy, physiology, and the kindred sciences. At the same time there are many facts that a man knows better immediately after graduation than he ever does again, and unless he has time and opportunity to carefully review such topics, he is not as able to stand an exclusively theoretical examination after some years of valuable professional experience as when he was a mere tyro.

The first civil service examination for medical positions under the City Government, exclusive of the Department of Public Charities and Correction, was held February 3d and 4th, at the rooms of the Civil Service Commission. There were forty-five applications made for positions, and thirty-nine actually competed at the examination. Of these, twenty-eight passed and eleven were rejected, not having reached the grade of seventy per cent. required for passing. Although a man's previous education and experience, to which he certified on oath, counted in his favor, the only actual test of professional knowledge to which he was subjected consisted of a written examination in which the time was limited. The subjects comprised all the branches of medicine and hygiene, but did not include outside topics. As a rule the questions were fair and leading ones. One objection, however, that caused much complaint was that the examination covered too much ground, and that not sufficient time was allowed. We have carefully examined the questions, and think there was room for such criticism. It is here that a man who is well posted, but not freshly crammed, has not altogether a fair chance, as he is not given sufficient time for reflection.

We think the fairest way of conducting such an examination would be to make it partly written and partly clinical and practical. In the written test the questions should be leading, and abundant time allowed for answering them; in the clinical part let the applicant be taken to a hospital or dispensary and his resources in diagnosis, prognosis, and treatment be put to a practical trial. In this way we think undue advantage would not be given to the merely crammed man. On February 9th the Civil Service Board was changed, and we understand it is the object of the present board to make future examinations as practical as possible. There are many difficulties attending the equitable adjustment of civil competitive examinations, but in course of time and after various trials we feel sure that a fair system will be elaborated, in which a happy combination of theoretical and practical tests, rationally applied, will result in the selection of the fittest man for office. A weak point of the present system in this city, is that when openings occur in any department, the three highest on the list are sent for each vacancy, but the appointing power is not obliged to select from this number, and can have repeated names sent, in classes of three, until a selection is made. In this way it is possible for men standing quite low in the list, but having strong political influence, to obtain an office. The fact that men who stand high on the list have not received a given position does not prejudice them from other appointments, however, as they still stand high on the list, and will accordingly have their names handed in first for the next vacancy in any department.

While the appointing power should have some latitude in making selections, according to the law in this city, the men who pass the best examinations do not necessarily get the positions. We would therefore offer as a suggestion, that in the future the examinations should be made as nearly as possible fair tests of the applicants relative abilities to practically fill a given office, and that then the successful ones should receive appointments in the order of their merit. If these details are not observed, the plan of appointing by civil service examination will be practically little better than by old-time political favoritism. The men who have recently passed will be on the eligible list for two years—after that, as the law now stands, their names will be dropped. In subsequent examinations, however, if any men pass better, they will take precedence. Any temporary position, as summer inspector of the Board of Health, does not preclude one from being eligible to a permanent position.

IS DENTISTRY A DISTINCT PROFESSION?

THE discussion on the retention of dead teeth in the jaws in these columns has elicited inquiries as to what constitutes "dentistry"; and inasmuch as efforts are being made to improve the means for dental instruction, the

subject has an interest for medical men. We learn from Dunglison that a dentist is "one who devotes himself to the study of diseases of the teeth and their treatment." They have also received the designation of dental surgeon, and surgeon-dentist. The work of the earlier dentists was confined mostly to tooth-drawing, the stopping of cavities in teeth, and the application of false teeth. Their ranks were recruited from among skilled artisans, notably goldsmiths, sources from which many continue to come. For the past quarter of a century dentists have been organizing themselves into associations, and some twenty "dental colleges" have come into existence. From the brotherhood of these associations soon came into existence the so-called "dental profession." In the meantime there has been now and then an accession to their ranks of men possessing more or less knowledge of diseases of the mouth, who have attempted to raise the business of dentistry to the dignity of oral surgery. It will thus be seen that the "dental profession" is constituted of two distinct elements, a mechanical and a medical. Now it may be said of the former that in the public mind they are by courtesy a "profession" much in the same sense that barbers are, since the one cannot display greater zeal in recommending his hair invigorator to patrons in his chair than does the other in respect to his dentifrice. But it is otherwise with the medical men who have espoused dentistry, and who, while reaping the harvest of profit that comes from dental ornature, as well as from surgical treatment of the mouth, desire to dignify their avocation with the title of "Oral Surgeon." Just here we will venture to offer a word of counsel to those whose inclinations lead them to the practise of oral surgery, some of whom seem anxious to elevate the standing of all dentists to their own; it is this, the attempt to educate persons at the outset as dentists is commencing the work at the wrong place. A specialist in medicine cannot thus be made; there is no short cut for the oral surgeon any more than there is for the ophthalmologist or the gynecologist.

We by no means desire to be understood as opposed to any real advance in any departments of medicine, and, therefore, shall welcome all laudable efforts made in this direction, which, of course, includes oral surgery; and we trust that opportunities may not long be wanting for those whose tastes or interests induce them to take up this specialty after acquiring a medical education. The "dental college," which we believe is peculiarly an American institution, and an outgrowth of a desire to promote the interests of the "dental profession," cannot in its present state do more than instruct the student in a most superficial way as regards medicine, but it may give him special knowledge, and we would suggest that its work should be confined to this. The instruction might include all that would be of service to the metallist both in respect to chemistry and smith-craft. In this way could much be done to prevent the introduction of harmful metals into the mouth in the way of plates or fillings, and the application of ill-fitting plates and other appliances.

The attempt to educate men as oral surgeons, and confer a degree upon them as such in a college, would be as absurd as the exclusive education of an ophthalmologist in an "Ophthalmological College." It is a mistake to suppose that oral surgeons constitute a "profession" any more than do laryngologists or gynecologists in medicine, or patent or criminal lawyers in the law. An oral surgeon must first learn the medical art, just the same as if he were going to practice on any other region of the body.

As regards the making of plates for false teeth or other mechanical work, the oral surgeon may certainly do this, as physicians and surgeons may dispense their own medicine and make their own surgical appliances, since these are all matters concerning each individual's taste or skill.

And while we are on this topic, if the truth must be said, it is high time that all specialism in medicine, inclusive of oral surgery, should have some limitation, since there is a growing tendency toward making all of them "professions," with the consequent practice of greatly overdoing local treatment; this seems specially imminent where the public has become unduly "educated" up to the importance of the local treatment of disease of special organs.

There is another feature of this question which should interest physicians; laws are being enacted in nearly all of the States which to a greater or less extent limit the practice of oral surgery, or dental surgery as it is sometimes called, to the graduates of dental colleges, thus practically throwing the treatment of an important region of the body into the hands of men who, in most instances, have not a sufficient medical education. Physicians are themselves much to be blamed for this state of things, since they have long been in the habit of relegating the treatment of diseases of the mouth to the "dental profession." Should the various specialists finally resort to this kind of trades-union protection, there will soon be no further use for the general practitioner.

THE PRESENT STATUS OF THE CHOLERA BACILLUS CONTROVERSY.

Medical men seem to be thoroughly in earnest this time about reaching bottom facts with regard to cholera. Observations, experiments, and conclusions are showered upon us with lavish liberality. Regarding the vital point of the origin of cholera, opinions are almost as widely different to-day as they were twenty years ago.

One fact, however, stands out boldly before us. Koch has demonstrated the constant association of certain organisms with Asiatic cholera. But the precise relationship which these microbes bear to the disease, and even their diagnostic significance are still in dispute.

In Dr. Wendt's paper, published elsewhere in our columns, we find a *résumé* of some of the most recent inquiries into the nature of cholera. The latest experiments of Van Ermengem would certainly seem to prove that Koch's commas are possessed of virulent properties. But we have not yet learned that all the other intestinal bacteria found in the discharges of cholera-patients are innocuous. The investigations of Emmerich may not have been carried out with the nicety and precision of a Koch, but we fail to see that they deserve no serious consideration.

The report of the British Cholera Commission we confess to be, so far, quite disappointing. The English in-

quirers cannot certainly be accused either of incompetency or of bad faith. Yet they appear to have learned absolutely nothing new about cholera, except that Koch's theory should be at once discarded as not in accordance with (their) ascertained facts. The English report emphatically negatives every one of the German mycologist's assertions (except the constant occurrence in cholera of comma bacilli). The published results of their labors do not in the least assist our understanding of the nature of the disease.

Now, it is very embarrassing to find competent and diligent search for truth lead to such contradictory statements as are found in Van Ermengem's account of his experiments, and the English Commission's report of quite similar ones.

Dr. Wendt, we notice, rather evaded the main issue by merely emphasizing that comma bacilli always occur in cholera. What we wish to know now, and what appears so difficult to determine, is, what the finding of Koch's microbes really amounts to. Is it quite safe to rest a responsible diagnosis upon the identification of these minute and apparently fragile bodies? And do they actually kill thousands of human beings by their extreme virulence?

We must confess that Koch's doctrine has the great advantage of being positive, plausible, aided by analogy and circumstantial evidence, and, further, supported by the accumulating evidence of independent investigations. But in spite of all this in its favor, we have the positive assertions of other inquirers, which are entirely subversive of Koch's statements. At present, therefore, the complete doctrine of Koch cannot be accepted in the sense of a perfect scientific demonstration. As a theory, it is good and serviceable. As a practical guide for treatment or prevention, it must await the ripening that time alone can bring, or, in the words of Chapman, it will have to subside "into the Lethe, which, during the last fifty years, has engulfed hundreds of parasitic fungi which had played a like rôle."

THE PRESIDENT-ELECT AND CHOLERA PREVENTION.

It is now apparent that nothing will be done to protect the country against the invasion of cholera, at all adequate to the emergency, until after March 4th. Although valuable time will be lost which can scarcely be retrieved, yet it may be possible to organize the necessary machinery and put it in successful operation, provided energetic measures be at once adopted. The Sundry Civil Service Bill appropriates the unexpended balance of last year, together with the additional sum of $300,000, the same to be immediately available, to be used at the discretion of the President. The most encouraging feature in the present situation of public affairs, as far as they relate to cholera-prevention, is the approaching change in the office of the Executive of the nation. President Arthur has signally failed to recognize the great responsibility resting upon him in the proper employment of the Epidemic Fund to avert a threatening invasion of cholera. He has had it in his power to have had prepared and put into execution, by the National Board of Health, a system of preventive measures which would have saved the country from this pestilence. The fund placed at his discretion has, on the contrary, been frittered away, and nothing adequate to the occasion has been done, or even contemplated.

We have great faith in President-elect Cleveland, who is a man of straightforward methods, and of practical ideas. We believe that he will at once, on assuming office, correct the errors of his predecessor, and judiciously employ every means at his command to bring the great powers of the Government into active co-operation with State and local health authorities to prevent the threatened epidemic of cholera.

POISONOUS WALL-PAPERS.

The report of Dr. Wood to the State Board of Health of Massachusetts, in which it was stated that from one-half grain to seven grains of arsenic were found per square yard in certain samples of wall-papers, being supplemented by reported cases of arsenical poisoning in Europe from this cause, and an actual case in this city being now under treatment, it has been decided by the New York Board of Health to make a thorough investigation into this subject.

From inquiry we have made there can be no doubt that, with one exception, *all* grades of colored wall-papers manufactured in the United States contain more or less arsenic. This practice of introducing a poisonous substance into a covering for walls is the more reprehensible from the fact of its being totally unnecessary. One firm in London, England, and one in New York produce wall-papers having the most varied and brilliant coloring, which have not even a trace of arsenic in their composition, and there appears to be no reason for other manufacturers using poisonous colors, except that by doing so they make a higher profit on their manufactures.

Arsenical colors are strong and about half the price of non-arsenical colors, and herein lies the secret of their persistent use by wall-paper manufacturers, and it appears to us that action by the Legislature is called for to put a stop to the practice.

We find, also, that a class of colors used by wall-paper manufacturers (who claim to sell non-poisonous wall-paper), which have not arsenic as a base, really contains much of this substance. We refer to colors composed of some white compound, such as whitening, as a base, which is stained with aniline. These colors are very largely in use, and, of course, contain arsenic introduced with the aniline.

The vehicle usually employed to give body and adhesiveness to the coloring being glue, often made from hides prepared with arsenic, this substance is constantly introduced by such means.

It is therefore clear that the practice followed by the firms in question, of employing permanently an expert chemist, who tests every package of color and glue by the Marsh test, which indicates the presence of the twenty-thousandth part of a grain, is the only method by which non-arsenical wall-papers can be produced.

The public appear under the impression that arsenical poisoning from wall-papers is due to portions of arsenic in powder being dusted off the walls. Such is not the case, the chief danger lies in the fact that, in damp

weather, the arsenic undergoes decomposition, and forms, in combination with other substances present, arseniuretted hydrogen, which diffuses in the room, and being a deadly poison causes sickness to the inmates. This form of arsenical poisoning is more to be dreaded than that from the particles removed by attrition; the latter, however, being also a source of danger to health.

In conclusion, we would point out that the common belief that arsenical colors are restricted to green, is by no means correct, for the blues, browns, yellows, and reds are largely contaminated with this poison.

We are glad to hear that Dr. Edson, on the part of the New York Board of Health, has determined to sift this matter to the bottom, and we shall await the result with much interest.

LARYNGEAL STENOSIS AND CERTAINTY IN MEDICINE.

A BRIEF discussion which occurred in the New York Pathological Society, on December 24th, should become historical. A distinguished professor of children's diseases asserted that in laryngeal stenosis (of croup) the respiration was slow. Another eminent gentleman, also a professor of children's diseases, and almost equally well-known, asserted that in the condition referred to the respirations were invariably hurried. One professor had seen a hundred cases, "and many more;" the other had seen four or five hundred cases; yet upon a simple clinical phenomenon there is absolute divergence. The lesson suggested at the time was that one must see a great many cases of a disease in order to establish a clinical fact. We do not quite agree with such a view. It is better to see fewer cases and study them well. In this we are supported by the fact that the gentleman who saw the fewer cases of croup has drawn the correcter conclusion regarding the effect of the disease upon the respiration.

THE PREVALENCE OF NERVOUS DISEASES.

A DISPENSARY for nervous diseases has recently been opened in Brooklyn under the auspices of prominent local physicians. In their announcement the gentlemen interested give a number of statistics for the purpose of proving the great prevalence and fatality of nervous troubles. Good wine needs no bush, and a good work needs no alarmistic or exaggerated utterances to preface it. It is one thing to supply a want, but quite another to createa want for the sake of meeting it We are told that the death-rate from nervous and mental diseases is about 20 per cent. of the total death-rate in Brooklyn, and that nervous diseases are only surpassed in prevalence by zymotic, tubercular, and respiratory diseases.

We must believe that Brooklyn is a very nervous place. In New York City the Board of Health report for 1875 showed that only 7.93 per cent. of the deaths was due to nervous and mental diseases, and that of this number 5.29 per cent. was due to meningitis, convulsions 2.00, and apoplexy 1.20. Apoplexy is a vascular disease; convulsions and acute meningitis belong to general medicine. This leaves only a paltry 2.64 per cent. of deaths due to the class of diseases ordinarily treated by the alienist and neurologist.

Doubtless there is a need of more special opportunities for the treatment of those suffering from nervous diseases, but it is not necessary to create the impression that these diseases exist in an alarming frequency.

DENTAL CHARITY.

DR. ROOSA struck a happy note at the dinner of the Odontological Society last week, when he urged that dentistry, being such a prosperous calling, should now do a little more for charity. There is no reason why a man should receive gratuitous treatment if he has a pain in the stomach, but none if he has a pain in his tooth. He can, to be sure, have his tooth pulled out without paying, but that is about the limit to which dental charity has as yet reached. The dental departments of our city dispensaries consist generally of a box of second-hand forceps, which are wielded by young amateurs with a generous indiscrimination, and with varying degrees of skill. Such kind of dental charity may be compared to a surgical charity, which is supplied simply with a saw and a knife for cutting off all bruised or injured fingers, without making any finical distinctions as to degree or kind of traumatism. There are annually in this city not far from ten thousand teeth wrenched from the poor man's mouth in the name of charity. How much discomfort, dyspepsia, and domestic troubles this produces we will not attempt to estimate. Certain it is that the teeth of the poor get a great deal less care than they ought to have, and are more abused, surgically speaking, than any other organ of the body. In the name of charity, let the poor be taught how to preserve their teeth, and let the clean mouths, at least, be given a chance to have their good members saved.

News of the Week.

THE ANNUAL KIRMESS in aid of the charity fund of the New York Skin and Cancer Hospital will be held at the Metropolitan Opera House on April 14th and 15th. National booths, presided over by ladies in characteristic costumes, will be a prominent feature. Three national dances will be given each evening.

DEFENDING THE REGISTRATION LAW.—According to an Associated Press despatch, the first indictment ever returned in Minnesota against physicians practising without a license was brought in on February 19th against Dr. Spinney, a specialist, formerly of Chicago. It is the intention of licensed physicians to push the matter to the full extent. Spinney was arraigned in court and held under bonds for appearance.

A PHYSICIAN KILLED BY AN OVERDOSE OF MORPHINE.—Dr. William Donald, physician of the steamer State of Nebraska, was found dead in his bed at Earle's Hotel, February 19th. He had been a sufferer from kidney troubles and was in the habit of taking morphine. There was nothing to indicate that he had committed suicide. He was twenty-seven years of age, and was born in Glasgow, where his father is a prominent physician.

DR. THOMAS R. POOLEY has resigned his position as Assistant Surgeon to the New York Ophthalmic and Aural Institute.

Dr. P. Brynberg Porter succeeds the late Dr. Gaillard as editor of *Gaillard's Medical Journal*. Dr. Porter's experience, scientific and literary acquirements, will doubtless develop an accomplished editor, and the proprietors of the journal are to be congratulated on their selection.

A State Board of Health for Maine.—The Maine Legislative Committee gave a hearing, February 6th, to advocates of a State Board of Health, a bill to establish which is now before the Legislature. The State Medical Society favors the bill.

Cremation in Massachusetts.—A bill has been introduced into the State Legislature of Massachusetts incorporating the "New England Cremation Society," for reducing bodies of the dead to ashes. The capital is $25,000.

The Commencements Begin.—Rush Medical College held its annual commencement on February 17th, and graduated a class of one hundred and fifty-one. The college term is a little less than five months.

Dr. William Braithwaite, editor and founder of *Braithwaite's Retrospect*, recently died in his seventy-eighth year.

Women as House Surgeons in the Paris Hospitals.—Another victory is scored for medical women. The question of admitting women as house surgeons in hospitals has been favorably considered by the Conseil Municipal of Paris. For their admission 48 votes were recorded, and 28 against. M. Hamel proposed that a separate living-room should be set apart for female house-surgeons. This proposition was also adopted.

The Annual Report of the New York Quarantine Commissioners was presented at Albany on the 24th. The sum of $24,500 is asked for in order to prepare against the cholera.

Dental Charity Abroad.—The teeth of all children attending the communal schools in Brussels are examined by order of the State, and during the year 1882–83 no fewer than 1,250 pupils required the services of the dentists. In England the managers of the North Surrey District School, Anerley, England, have appointed a dentist to attend weekly in order that the children may have proper attention paid to their teeth. The question is whether the dental services above referred to are limited to tooth-pulling.

Obituary.

PROFESSOR LOUIS ELSBERG, M.D.,

NEW YORK.

In the death of Dr. Louis Elsberg, of this city, the medical profession loses one of its most active and distinguished members. He was a most enthusiastic worker in laryngology, in which branch he was the pioneer in New York. Dr. Elsberg was born at Iserlohn, Prussia, April 2, 1836; his death occurring in his forty-eighth year. His parents came to this country during his boyhood, and his early life was spent in Philadelphia. His academical education was obtained at the college there, where he graduated with honors. His medical diploma was from Jefferson in 1857. His fondness for physiological study, and particularly for that of the human voice, at once turned his attention in that direction. It was at this time that Professor Czermak, of Pesth, demonstrated the practical value of the laryngoscope as a means of diagnosis, and Dr. Elsberg went to Vienna, where, with Stoerck, of Vienna, Lewin, of Berlin, and Semeleder, he formed Czermak's first class of pupils. All of these men have since become noted in their profession. Dr. Elsberg returned to New York, and immediately commenced practice in this specialty. He became a member of the faculty of the University Medical College in 1861, and retained this position for seventeen years. In 1862 he established in this city the first clinic for diseases of the throat. During the whole of his life he was a very frequent contributor to the journals of medicine, and took a very active interest in the various medical and scientific societies to which he belonged. He was a member of the County Society, Academy of Medicine, Pathological Society, American Medical Association, Academy of Sciences, American Laryngological Association, etc. For some years he was the librarian of the Academy of Sciences. He was devoted to biological study, and in this connection was an earnest microscopical worker. In 1878 he read before the Academy of Sciences a very exhaustive treatise on "The Structure and other Characteristics of Colored Blood-corpuscles," a paper which showed a vast amount of original thought. He delivered the annual address before the Alumni Association of Jefferson Medical College in 1882, it being, as he expressed it, "the silver wedding of his class." His paper was "Changes in Biological Doctrines during the Past Twenty-five Years." In June, 1878, he, with other gentlemen, founded the American Laryngological Association, and he was elected its first president. At the first meeting of this Association he gave a comple "History of Laryngology." His address at the second meeting, on "Laryngological Instruction," was sent from Aix-la-Chapelle, where he had gone to regain his health. In March, 1880, he began the publication of the *Archives of Laryngology*, which was a quarterly, published by the Putnams, and was continued till 1884. Among other productions from his pen were "Laryngoscopal Surgery," an essay which was based upon a large number of operative cases, and which received the gold medal for 1865 from the American Medical Association, "Microscopical Study of Papilloma of Larynx," etc. He had collected a large amount of material for a book, which he had intended to publish. After severing his connection with the University Medical College he became Professor of Laryngology at Dartmouth, and this, together with the similar chair at the Polyclinic, he held at the time of his death.

Dr. Elsberg's aptitude for acquiring knowledge was very great, and his capacity for retaining it was most remarkable, which gave him at an early age a most enviable position among medical writers. He was an untiring student, which fact, to a large extent, was the cause of the illness he suffered during the last years of his life. In 1880 he went to Europe by the advice of his physician, and returned greatly benefited in health, but close application to business caused a recurrence of his old trouble—Bright's disease—and eventually caused his death.

Alum acts as an astringent by forming insoluble compounds with albumen, gelatine, and casein. Some give it in an excess of dilute sulphuric acid, especially in painters' or lead colic, for which it has been used for over one hundred years. It mitigates pain, relieves flatulence, and generally acts with certainty as an aperient. It is also a far better germicide than sulphate of iron.

Citrate of Ammonia is a much more pleasant remedy than the acetate, unless the latter is made with remarkably good vinegar, or pure dilute acetic acid.

Reviews and Notices.

Elements of Surgical Diagnosis. By A. Pearce Gould, M.S., M.B., London. 12mo, pp. 584. Philadelphia: H. C. Lea's Son & Co.

This is a capital little book, written by a practical man on a very practical subject. The topics are very systematically and succinctly arranged, are tersely presented, and the points of diagnosis very intelligently discussed. It will be found to be of the greatest amount of help both to teacher and student.

The Principles and Practice of Dentistry, including Anatomy, Physiology, Pathology, Therapeutics, Dental Surgery, and Mechanism. By Chapin D. Harris, M.D., D.D.S., late President of the Baltimore Dental College. Eleventh Edition. Revised and Edited by Ferdinand J. S. Gorgas, A.M., M.D., D.D.S. 8vo, pp. 994. Philadelphia: P. Blakiston, Son & Co.

Dr. Gorgas has done his best to bring this work up to its high standard as an authority on dentistry. In this he has fulfilled the purpose of the late Dr. Harris, and his labors will be appreciated accordingly by the dentists throughout the country. For it is to such only that the volume appeals. Mechanical dentistry has deservedly the fullest share of attention, and the details of this department are very plainly presented. From this point of view no criticism can be offered. The chapters on treating the teeth, filling dead teeth, plugging diseased cavities, and similar operations, although eminently sound, dentally speaking, are not in strict accord with what surgeons generally are willing to accept as advanced pathology. The author and editor believe what they say in reference to these matters, but we believe they are wrong nevertheless. Although there is a tendency to conservatism in the treatment of pulpitis, the inevitable plug is in the background, and is introduced on every possible opportunity. But such has been the settled opinion for the last quarter of a century, and it will be hard, for the present at least, to change the views.

The numerous complicated operations upon the mouth are judiciously omitted, belonging as they do to general surgery. There is a single exception to this in staphylorraphy.

The Diagnosis and Treatment of Chronic Nasal Catarrh. Three Clinical Lectures, delivered at the College of Physicians and Surgeons, New York. By George Morewood Lefferts, A.M., M.D. 12mo., pp. 49. St. Louis: Lambert & Co. 1884.

This little brochure presents in the author's well-known systematic manner three practical chapters on the examination, diagnosis, and treatment of this pen-ridden disease. There are thirty-five illustrations of instruments and pathological appearances, and a few formulæ of sprays, powders, and washes that have proved useful in the author's hands. For simplicity and the avoidance of useless expense Dr. Lefferts' recommendations as to instruments and apparatus may be safely followed by every practitioner.

Under the head of treatment the author properly inveighs against the too prevalent use of saline solutions with the nasal douche. It propagates chronic rhinitis, and establishes permanent infiltration of the mucous and submucous tissues. The author prefers the spray to powders, as a means of medication. Among the pharmaceutical formulæ Listerine forms an important factor; each fluidrachm of which contains two grains of purified benzo-boracic acid, besides the antiseptic constituents of thyme, eucalyptus, gaultheria, etc. The author prefers the high pressure of compressed air to the lower power of the hand-ball atomizer, believing that only by the former all the irregularities and crypts of the upper pharyngeal passages are reached; he condemns the forcing of a cotton-holder charged with nitrate of silver up behind the velum palati, as also the post-nasal brush. Among destructive agents in the treatment of hypertrophic rhinitis he recommends the following in the order here placed: fuming nitric acid, glacial acetic acid, chromic acid, the galvano- or actual cautery, and nitrate of silver: the last is condemned as a destructive agent. Jarvis' écraseur, and, for adenoid growths of the pharynx, the post-nasal forceps are added. We cannot agree with the author in the license with which he commits the last-named instrument into the hands of his readers, on account of the destruction of healthy mucous membrane, which has sometimes attended the eruption of adenoid growths at the vault; we wish, too, he had given more encouragement to the local treatment of fetid rhinitis, for some cases are curable.

The little brochure is welcome as one of the best treatises of a trite topic that has fallen to our hands; its compactness, system, and practical views recommend it to every practitioner.

The Law and Medical Men. By R. Vashon Rogers, Jr., of Osgood Hall, Barrister-at-Law. 8vo, pp. 214. Toronto, Canada, and Edinburgh, Scotland: Carswell & Co. 1884.

The author modestly states that his book is intended to be suggestive rather than exhaustive—a primer, not an encyclopædia. Despite this estimate, we think that the physician will find in it sufficient for ordinary emergencies, and for the rest he would probably consult a lawyer any way. The subjects discussed are those of Fees, Who should Pay the Doctor, Who may Practise, Negligence and Malpractice, Criminal Malpractice, Professional Evidence, Experts, Defamation, Relations with Patients, Dissection and Resurrection, Dentists, Druggists, Partners. These different matters are discussed briefly, the law is laid down, and many illustrative cases are cited.

The book seems in reality to fill a gap, although the larger treatises on legal medicine cover many of the subjects treated.

The Brain and Nerves: Their Ailments and Their Exhaustion. By Thomas Stretch Dowse, M.D., F.R.C.P.E. 8vo, pp. 150. Second Edition. New York: G. P. Putnam's Sons. 1884.

We do not know why the author of this little work gives it the title of "The Brain and Nerves," since it is really a treatise on nervous exhaustion, in which certainly the spinal cord and other extra-cranial centres are also involved. However, it makes little difference, since he admits to his subject in the preface and plunges at once into a discussion of its importance and its nature.

Dr. Dowse begins with a plea for the more serious study of neurasthenia by medical men. He discusses the well-known objection that "harm is done by bringing before the patient's view the signs, symptoms, and associations of nervous exhaustion," and that they often by this means become chronic hypochondriacs. Dr. Dowse believes, on the contrary, that the worst enemy of the emotions is the intellect, and by getting a patient intellectually interested in his own case, we can put him in a position to more surely recover. This is much the same view as that taken by the late Dr. Beard—whom, by the way, our author liberally quotes. It is certainly a just view as applied to the majority of cases. If only doctors were all scrupulously honest, and patients persons of good sense, it would apply always.

Dr. Dowse goes into a learned discussion of the dynamics of nerve-force and the ultimate nature of nervous exhaustion. He is interesting, but we can hardly admit that the reader will get much help out of his italicised and generally rather trite enunciations. The most of the book is devoted to the subject of the symptomatology and therapeutics of neurasthenia. Here the author writes well and helpfully. He has evidently seen many cases, and understood their nature and management. His book is unquestionably a very useful addition to the literature of a most obscure subject.

THE STORY OF MY LIFE. By J. MARION SIMS, M.D., LL.D. Edited by his Son, H. MARION SIMS, M.D. 12mo, pp. 471. New York: D. Appleton & Co. 1884.

To write biography is confessedly one of the most difficult essays in authorship; how great a task, then, does he impose upon himself who ventures to compose the story of his own life. If the autobiography be worth the writing, the author must have accomplished something worthy of recording; and to avoid the Scylla of self-adulation on the one hand and the Charybdis of self-depreciation on the other, requires indeed a well-balanced as well as a fearless mind. Fortunately for himself, as well as for his readers, Dr. Sims possessed both these qualities in an eminent degree; and the result in the book before us is the history of a great man who accomplished in his lifetime grand results, told in a manner which reflects his character and justifies his achievements. The work is but partial, only reaching to the year 1861; but it records his early struggles and brings us to a glimpse of his world-wide success.

If he had been allowed to follow his own early inclination he would never have undertaken the study and practice of medicine, but would have been content with the lot of a country store-keeper; but his father insisted upon his receiving a university education. Still, in the midst of his educational career, he endeavored to return from college to his home life, and only the command of his mother compelled him to resume his studies. Having graduated, he was forced to choose between law, ministry, and medicine, and he selected the latter only because it was the least distasteful to him. His first attempt at practice in his native village was an utter failure, and he left his birthplace chagrined and almost disheartened. An assemblage of fortunate circumstances gave him the first opportunity to acquire the necessary practical skill and self-confidence; and at Fort Meigs, and afterward at Montgomery, he established himself as a successful surgeon with a considerable local reputation. It was at the latter place that, quite accidentally, he came upon the principle as a result of which he invented the speculum which bears his name, and where he perfected the operation for vesico-vaginal fistula which gave him his first renown as a gynecologist. His health forced him to leave the South and he settled in New York, where his first labor was in the founding of the Hospital for Diseases of Women, in which he was ultimately successful after many discouragements and much opposition from those whose aid he had confidently relied upon. From this point on his professional career was one of continued brilliancy both here and abroad.

But the most valuable portion of the book is that which reveals to us the private and inner life of the man; and it is the manner in which this is told that gives the book the absorbing interest of a romance. The anecdotes of his school-days and of his early life; of his courtship and his marriage; the description of his hardships and failures; of his illnesses and his recoveries; of his struggles and his successes, reveal to us the character of the man of genius, full of energy, proof against the severest disappointments, sustained by the consciousness of his own honesty and of the mission which he was called upon to fill. His attachment to home, the beauty of his domestic life, and above all his love, amounting almost to adoration, for his wife, the sweetheart of his earliest years, present a picture which once seen can never be forgotten.

As was to be expected in a work written largely from memory, there are many inaccuracies in the book. Thus he states that he offered the position of assistant-surgeon to the Woman's Hospital to Dr. Shrady before Dr. Emmet; whereas the former was at that time not yet a graduate, and when he, Dr. Shrady, was offered the place, Dr. Emmet had already been connected with the institution for some time. But slight blemishes such as lapses of memory and faults of style, while they may detract from its historic accuracy and literary value, do not make his "story" any the less interesting as the pen-picture of the father of modern gynecology.

The introduction, by Judge T. J. Mackey, is useful as completing in a categorical manner the history of Sims' life; but it is marred by being pervaded by that style of fulsome eulogy which is the great bane of the biographer. In this case it is all the more noticeable because it is in such glaring contrast to the modesty and straightforwardness of the body of the book.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 23, 1885.

DANIEL LEWIS, M.D., PRESIDENT, IN THE CHAIR.

DR. JOHN C. PETERS delivered a lecture on

CHOLERA, ITS MODE OF INTRODUCTION, ITS PREVENTION, AND TREATMENT,

in which he gave the history of the introduction of the disease into the United States, in different epidemics.

Attention was especially directed to the fact that it had been very difficult to find out the *first* case, whenever cholera appeared in any given locality, because the first *fatal* cases were very apt to occur among old residents and not among new-comers.

Dr. Peters traced the travels of cholera in its visits to Egypt, France, Italy, etc. Studying the map, illustrating the invasion of Italy, it appeared that the malarious districts were not affected, thus proving that malaria was not an aid to cholera. *Civic malaria*, however, as Dr. Peters designated it, the influence of emanations from the combined filth of cities, he regarded as a very powerful ally of Asiatic cholera, while pure swamp malaria did not, at least, favor its introduction into any locality. Cholera was not carried by winds nor ocean currents, nor earthquakes, but by ships, and persons, and clothing, armies and pilgrims, and agencies of that kind. The first record of cholera dated back to 1503, in India. While tracing the travels of the disease, it was shown that the pestilence at one time invaded Denmark, also Greece, in consequence of lack of quarantine. Prevention pertained chiefly to the thorough adoption of sanitary measures.

Dr. Peters believed that no person was attacked with cholera who did not have the poison introduced into his system by the way of the throat. He also believed that it was impossible to diagnosticate, in many cases, between summer diarrhœa and cholera, although a large number of cases of summer diarrhœa had nothing whatever to do with cholera. It was safe, however, especially when cholera was about, to treat every case of summer diarrhœa as though it was to become cholera.

With regard to treatment, see article published by Dr. Peters in THE MEDICAL RECORD, February 21, 1885.

DR. EDMUND C. WENDT then read a paper (see p. 225) on

RECENT RESEARCHES IN CHOLERA.

DR. CYRUS EDSON, from the Committee on Hygiene, reported on

THE ARTESIAN WELLS OF THE CITY AS AFFORDING POTABLE WATER,

and pointed out the dangers which attend the use of contaminated water, and the ways in which potable water was liable to become contaminated.

DR. F. R. STURGIS gave notice that he would call upon the Board of Censors, at the stated meeting to be held March 23d, to explain why the Society lost its case against one "Dr." Jacques, alias "Dr." Kahn, alias "Dr." Jordan, tried in the county of New York during the month of February, 1885.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 19, 1885.

A. Jacobi, M.D., President, in the Chair.

ELECTRICITY AS A STIMULANT IN CARDIAC AND RESPIRATORY FAILURE.

Dr. Gaspar Griswold read a paper on the above subject, beginning with the statement that electricity had been conspicuous in the treatment of sudden prostration attended with respiratory and cardiac failure, especially in chloroform inhalation and opium-poisoning. The object of the paper was to discuss how far the usual methods of applying electricity in such cases of collapse were in accord with what was known concerning the physiology of the heart. The term electricity was used in a general sense, including galvanism and faradism.

Can electricity be so applied as to stimulate the heart? Prefatory to the answer to this question the author of the paper gave a brief synopsis of the cardiac mechanism, directing special attention to the effect produced by stimulating the pneumogastrics. From the study of this mechanism the conclusion was reached that, to stimulate the heart, the electrical current must be applied directly to the heart itself, and that the application of the poles to the neck over the pneumogastrics must be to produce an effect the reverse of stimulation. The question must, therefore, be answered in the negative.

Dr. Griswold then entered into the study of the effect produced when electricity was applied to the phrenic nerves, and reached the conclusion that electricity applied to the phrenic nerve stimulates respiratory movements.

On physiological and clinical grounds, therefore, stimulation of the phrenic nerve by itself was a proper and logical treatment in respiratory failure, but stimulation of the phrenic nerve could be scarcely considered separately from stimulation of the pneumogastrics, because these nerves were situated so closely to each other in the neck. In other words, electricity could not be applied to the phrenic nerve to stimulate contractions of the diaphragm without great danger of retarding or cutting off the function of the pneumogastric.

The conclusions, therefore, of the author of the paper were as follows: 1. Electrical stimulation of the phrenic nerve should not be undertaken without the reflection that the current will at the same time reach the pneumogastric. 2. Only mild currents should be applied, and their effects carefully watched, but especially with reference to the heart. 3. The sudden and careless application to the neck of a current sufficiently strong to produce pain or muscular contractions in other parts of the body, should be especially avoided.

Dr. Griswold then gave a detailed description of experiments which he had performed in dogs with special reference to the effects produced on the pneumogastrics, both by electricity and by drugs administered in poisonous doses.

ACONITE-POISONING.

The stimulant effect of electricity upon the pneumogastric in these cases did no harm, because aconite in poisonous doses produces paralysis of the pneumogastric. The application of electricity, therefore, to the phrenic nerve with proper care, in aconite-poisoning, was perfectly safe.

CHLOROFORM-POISONING.

Stimulating the pneumogastric caused fatal results at once. When heart-failure occurred early in chloroform administration, the pneumogastrics were still normally excitable, and at such times a very mild electrical current would instantly paralyze them and fatally depress the action of the heart. Therefore, it was immensely dangerous to apply electricity to the neck of a person poisoned with chloroform, and also when applied over the phrenic nerve it would almost certainly cause a fatal termination.

ASPHYXIA FROM ETHER.

In this condition the heart could stand stimulation as well as in health, and, therefore, it was safe to stimulate it with the strongest electrical current which the patient could bear in health.

Chloroform was a direct cardiac depressant; ether did not depress the heart.

OPIUM-POISONING.

Morphine in poisonous doses paralyzes the pneumogastrics, and stimulation of them by electricity would not slow or depress the action of the heart.

In opium-poisoning, when the action of the heart was rapid and feeble, there was less danger than in health of cardiac paralysis from stimulation of the pneumogastrics. When

MORPHINE WAS INJECTED INTO THE VEINS

the heart was easily depressed by electricity applied to the pneumogastrics, and it would not, therefore, be safe to faradize or galvanize the phrenics in this condition, because of the certainty, almost, of stimulating at the same time the pneumogastrics.

A general conclusion reached by the author of the paper was that, under no circumstances, should an electrical current, sufficiently strong to produce contractions of the muscles in any part of the body, be applied over the phrenic or pneumogastric in the neck.

Dr. A. D. Rockwell, in general, quite agreed with the statements made by Dr. Griswold, in his valuable contribution to the literature of this subject. The fact that, in the normal condition, and by purely external methods of application, the respiration was affected, rather than the heart's action, was very readily demonstrated. In connection with this subject, he might have referred to the statements made long ago by Arloing and Tripier, that the right pneumogastric had a more powerful influence over the heart, while the left more powerfully affected respiration. However that may be, it was certain that galvanization affected the two pneumogastric nerves unequally, and in a way to confirm, to some extent, that assertion.

It had been found that, if the heart be stopped by galvanization of the exposed left pneumogastric, the movements could be restored by some slight mechanical excitation, while, if the same result occurred through galvanization of the right pneumogastric, it seemed impossible to again excite the pulsations. These, certainly, seemed to be the effects of sedation rather than of stimulation, but that the effects that followed were powerfully stimulant and tonic could not be doubted.

Some years ago, in a number of experimental attempts in the electrolytic treatment of cancer, Dr. Rockwell had occasion to observe some interesting phenomena in regard to the primary and secondary effects of the galvanic current on the heart's action. In cases of scirrhus, after the breast had been removed by the knife, it was his custom to destroy, as thoroughly as possible, the underlying tissue by the electrolytic method. It was readily understood that the effects of this concentration of the current through needles penetrating the muscular tissue were much greater than any ordinary applications by means of sponges. The heart would slow up according to the tension of the current, and would sometimes become so alarmingly slow as to necessitate a cessation of the current for a time. The interesting point which was observed and commented upon by every physician who aided in, or was present at, those operations, was the fact that, following the breaking of the current, the heart's action became unmistakably more vigorous than at any previous time.

According to Professor Von Ziemssen, who made many carefully-conducted experiments by means of cardiographic tracings, induced currents have absolutely no influence on the frequency or force of the cardiac contractions, and from that fact the conclusion had been drawn that induction currents were valueless in threatening death from heart-failure. Dr. Rockwell's experience did not confirm that statement, for, in not a few instances of the kind he had known life to be saved by this form of electricity. The faradic current, by its power over the phrenic nerve, excited respiration, and so indirectly very decidedly influenced the action of the heart itself. He certainly agreed with Dr. Griswold in the necessity of caution in applications of galvanism to the region of the phrenic and pneumogastric, and it was better, perhaps, to err on the side of safety, yet Dr. Rockwell could not but think that Dr. Griswold somewhat overestimated the dangers attending these applications. One case he referred to briefly, since it conveyed an important lesson. Some years ago he saw with Dr. I. B. Read and several other physicians, a case of what afterward proved to be opium-poisoning. The respiration was only 10 and the pulse 40. On applying the faradic current the respirations immediately rose to 18 and the pulse to 70, but whenever the applications were withheld for a short time both respiration and pulse immediately fell to 10 and 40 respectively. For two hours, by means of electric excitation, the respiration and pulse were upheld, but at the end of that time they began to fail, notwithstanding their best efforts. At the end of four or five hours both respiration and pulse were so infrequent and feeble that the case was regarded as hopeless and abandoned. and on the following day he was surprised to learn that soon after the cessation of treatment the patient began to rally, and finally recovered. It was sufficiently evident that the patient had been kept alive for hours by the efforts made. The electricity had simply tided her over the hours when the poison was exerting its most depressing influence. It was a mistake to have abandoned the case when they did, and it should suggest to every practitioner that such cases should not be given up while the slightest evidence of life remains.

Dr. Fordyce Barker directed attention to collateral points, with special reference to the effects produced by chloroform and ether, as illustrated in obstetrics. The general conclusion which he had long ago reached was that ether was much safer than chloroform in surgical practice where the anæsthetic was administered to prepare the patient for an operation, whereas, chloroform was much safer than ether in obstetric practice where the anæsthetic was given to relieve pain already present. Furthermore, the early use of chloroform in obstetric cases was indicated rather than contra-indicated, when the woman had organic cardiac disease, contrary to the opinion that anæsthetics were not safe where cardiac disease existed. Dr. Barker had held this view and had carried it into practice during the last twenty-five years. But he would not use ether under the same circumstances.

Dr. R. W. Amidon wished to commend the remarks made by Dr. Griswold, and had nothing to offer in the way of criticism. He thought the paper was of the order which should receive the special commendation of the Academy, and made a motion to that effect, which was adopted.

Dr. Putzel thought that all the physiological deductions set forth in the paper of the evening were well put, but that the clinical inferences were not in accord with established clinical facts. The difficulty with most experiments on animals was that they could not be applied to the human body. He knew of no way in which the pneumogastrics could be galvanized in the human subject, aside from a surgical operation, because the current when applied to the surface diffused itself to an extent which did not permit us to speak of galvanization of the pneumogastrics; indeed the best galvano-therapeutists employed the term galvanization of the neck.

He had applied electricity from twenty good elements, the number which the author of the paper had regarded as almost certain to produce death, without producing any bad effect whatever, and in exophthalmic goitre without producing any change in the condition of the pulse. From the clinical standpoint, the subject was one which required revision, and the truth could be reached only by prolonged observation of cases.

It would not do to accept cases in the report of which it was simply said that "electricity was applied," as something should be known concerning the size of the electrodes, strength and kind of current used, etc.

Dr. J. Leonard Corning referred to cases of exophthalmic goitre in which galvanization of the pneumogastrics lowered the pulse-rate very markedly.

Dr. Putzel did not wish to be understood as saying that galvanization of the neck never produced slowing of the pulse, but simply that he had not observed that effect. He wished merely to state that galvanization of the neck was not galvanization of the pneumogastrics.

Dr. A. H. Smith thought that the object in view in the use of electricity in opium-poisoning was to stimulate respiration. This could be done by applying one pole over the phrenic nerve in the neck, and probably all the benefit which could be derived would follow the application of the current about sixteen or eighteen times a minute, and no more, and at the same time the dangerous depressing effect would be avoided. In the meantime, electricity could be used as a general stimulant, as was flagellation, etc.

The President referred to the use of electricity in the treatment of the asphyxia of the new-born. He had found it to be a valuable remedy in those cases, and had employed it as follows: When applied for four or five seconds in succession he had noticed that at the beginning the pulse and respiration were improved, to be followed by almost immediate paralysis. He had also found that this effect was produced the more surely when the application of the electrodes was confined to the region of the phrenic and pneumogastric nerves.

He therefore concluded, that the most practical way to use electricity was to apply it generally to the muscles, quickly striking the surface at different points with the electrodes. In opium-poisoning electricity was most effectual when applied at short intervals and by giving sudden shocks. At the same time, it should not be overlooked that in many cases cardiac failure was merely secondary to respiratory failure, and that when the respiration was improved by exciting the respiratory muscles, there would be a decided improvement in the action of the heart.

Dr. Griswold, in closing the discussion, reviewed the points made prominent in his paper, and said that he should prefer artificial respiration to general stimulation of the surface in the classes of cases under consideration. In chloroform cases, and those in which morphine had entered a vein he would not use electricity at all, but would rely upon hypodermic injection of stimulants, inhalation of ammonia, and artificial respiration.

Dr. M. Josiah Roberts then gave a description and demonstration of the working of his perfected

ELECTRO-OSTEOTOME,

with a new form of portable storage battery, and an electrical illuminating apparatus. The description of his first instrument was published in The Record, October 27, 1883. To further aid the surgeon in applying the instrument when surrounded by insufficient light, he recommended Jarvis's electrical light attached to a head-mirror.

The communication was discussed by Drs. Poore, Jarvis, Corning, Birdsall, Holcombe, and Fanning. The Academy then adjourned.

Muriatic Acid is said to prevent the development of intestinal worms.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 6, 1885.

W. J. MORTON, M.D., PRESIDENT, IN THE CHAIR.

ÆSTHESIOMETRY.

DR. GRACE PECKHAM read a paper on this subject (see page 230).

DR. DANA alluded to the general lack of precise knowledge concerning æsthesiometry, and thought that Dr. Peckham's instrument would aid in making matters clearer. The normal sensibility of the skin had been differently described by different authors. For practical purposes it seemed best to distinguish between common and special sensation. Temperature and pain belonged to the former. Special or tactile sensation revealed contact, pressure, and locality. So-called muscular sensation should be placed half-way between common and special sensation.

DR. BIRDSALL said that in Dr. Peckham's instrument the additional contrivance for estimating pressure was very valuable for purposes of careful physiological examination. It was necessary always to be very cautious about attaching diagnostic importance to the responses of patients. The practical use of ordinary æsthesiometry was limited to coarser tests. The additional estimation of pressure-sensibility might make the test more delicate and useful. Æsthesiometry might show that in a given case there was general slowness of appreciation, rather than actual tactile disturbance.

THE PRESIDENT thought that the instrument of Dr. Peckham might be further improved by attaching a scale in such a way that an accurate record would be had of the amount of pressure used. Unless this addition be made, different observers would necessarily record different results. With an agreement as to a normal standard of pressure this source of error would be obviated. In this way we might soon have a series of systematic observations, that would be a great help, especially in practical office examinations.

DR. PECKHAM remarked that her æsthesiometer was intended for the determination of cutaneous sensibility merely. The muscular sense would have to be tested in other ways. In order to have exact records of the amount of pressure employed, water would have to be used as a recording medium. This, however, would make a clumsy instrument, and one not readily carried in the pocket. Besides, æsthesiometry was intended, not for absolute, but only comparative results. If in place of a water-gauge, metallic springs were employed, they would yield after a certain time, unless very conscientiously tempered, which would make such an instrument too costly.

DR. B. SACHS then made some

REMARKS ON THE USE OF THE ABSOLUTE GALVANOMETER,

and demonstrated Hirschmann's new instrument. He insisted on the necessity of following the lead of English, German, and French investigators in adopting some unit of current strength. Hitherto the question had not received the consideration it deserved at the hands of American physicians.

The disadvantages of the old, or better said, the present method of gauging the quantity of electric force employed in any one case, must be apparent to all who are in the habit of using electricity either for therapeutic or diagnostic purposes. To say that we have used the electro-motive force of a certain number of cells gives but an imperfect idea of the actual current yielded, for the capacity of the cells, not only of different batteries, but of one and the same battery, varies greatly, and that too from day to day. To add the number of degrees to which an ordinary galvanometer was deflected, and the units of resistance which were introduced, does not improve matters much, for the deflection of a common magnetic needle does not increase in proportion to the strength of current employed, and with two variable factors in the calculation, a third, more positive one, loses much of its value. The physician who observes his galvanometer, rheostat, and battery, from day to day, may form a relative estimate of the amount of electricity used upon one patient or the other, but he cannot represent, to himself and others, the strength of current employed in terms of an intelligible unit.

After discussing the question whether it be absolutely necessary to exercise great accuracy and care in treatment, Dr. Sachs said that, for purposes of electrical diagnosis, there can be little doubt of the advantages which an instrument indicating the strength of the galvanic current passing through the body, in terms of a known unit, would possess over our present imperfect means of registering this amount. With the use of an *absolute* galvanometer we shall soon gain some definite conception of the current strength required to produce, say kathodic closure, contraction of any nerve or muscle, and to compare with this figure the current strength required to excite the same nerve or muscle under pathological conditions.

The reader then urged the adoption of the *milliampère* as a unit of measurement. This unit, first suggested by De Watteville some years ago, has come into general favor abroad, for it has been abundantly demonstrated that this unit and its multiples correspond quite accurately to the quantity of electricity generally employed for purposes of treatment or diagnosis.

Taking up the question of absolute galvanometers, it was urged against Gaiffe's and Edelman's instruments, and against all *horizontal* galvanometers, that the deflection of a horizontal needle varies with the difference of magnetic force at various points of the earth's surface. A current causing a deflection of ten degrees in Paris would not be equivalent to the current producing a similar deflection in New York or Berlin. Hirschmann has met this difficulty by employing, not a single horizontal needle, but a pair of astatic needles vertically adjusted.

In conclusion, the author contended that Hirschmann's vertical absolute galvanometer met all the following requirements: The instrument must indicate the exact strength of current passing through the body; and any deflection of the needle must be equivalent to one and the same quantity of electricity the world over. The instrument must be sensitive enough to indicate the passing of a current through any part of the body before the patient perceives the current. The needle must not oscillate excessively, and must come to rest quickly after the current is broken. The instrument must be substantially made, and lastly, must permit of an easy adjustment to all batteries, stationary and portable.

Dr. Sachs suggested also that our instrument-makers provide us with absolute galvanometers constructed upon the same principle as Hirschmann's and equally reliable.

DR. JACOBY had seen Hirschmann's instrument in active use, and was convinced that it was the most perfect apparatus of the kind yet devised. He believed it to be quite independent of terrestrial magnetism.

DR. BIRDSALL remarked that one objection to all vertical galvanometers consisted in the fact that their magnetic intensity might change. The skilled labor involved in constructing good apparatus of this kind had led American instrument-makers to avoid manufacturing them. He believed that the importance of the galvanometer was more apparent for purposes of accurate diagnosis than for therapeutical efforts. General practitioners had certainly been able to obtain beneficial results without resorting to the use of accurate current measurements.

DR. BERG said that the scale on the vertical galvanometer should not be made up, as in Hirschmann's instrument, of equal distances, as the factor of gravity was thus left unprovided for.

DR. SACHS pointed out that the instrument was particularly useful for general practitioners, who only made

occasional use of their batteries. The number of cells employed could not be a measure of the strength of the current. And in this way injury in place of benefit might result, especially whenever the head was concerned.

Correspondence.

THE DIAGNOSTIC VALUE OF THE SPECIFIC GRAVITY OF URINE.

To the Editor of The Medical Record.

Sir: The special correspondent of The Medical Record, at Vienna, in a late number (January 17th) refers, among other things, to two interesting cases, viz.: glioma cerebri and diabetes mellitus, taken from the clinic of Professor Nothnagel. Referring to the latter case, the writer, in closing, says: "The case is also a very instructive one, as a case of sugar in the urine without polyuria, and, what is more remarkable, with urine of a continual low specific gravity. Here is an instance of the value of the thoroughness of the German methods of examination before making a diagnosis. With such a low specific gravity the presence of sugar in the urine would certainly have been overlooked by an American physician, and thus an important aid in diagnosis, and a valuable symptom for treatment, have been lost." It is to the last sentence of the foregoing quotation that I wish to call attention, for if the statement there made be true (as it probably in too many cases is true), it is a matter of the greatest importance to every physician to whom it is applicable, and one that he cannot afford to overlook, but should speedily remedy.

There is probably in our country many a busy practitioner, who, to determine the presence or absence of sugar in the urine, contents himself with taking the specific gravity of the latter, and draws his conclusions therefrom, without making any chemical test whatever. Let us see whether such a method of examination alone to determine the presence or absence of sugar in the urine is advisable, and whether the conclusion drawn from such examination can be relied on. To this end we will first consider the specific gravity of healthy urine. Physiologists and physiological chemists tell us that although the average specific gravity of healthy urine is about 1.015 or 1.020, it can, under certain circumstances, be as low as 1.002 or as high as 1.030,[1] without containing anything of a pathological nature. Other writers put the maximum specific gravity of healthy urine higher. Wagner, for example, puts it as high as 1.040.[2] As is well known, the amount of fluids taken into, and given off by, the system, influences very decidedly the specific gravity of urine, and in the extreme figures already quoted, viz.: 1.002 and 1.040, the difference was due in the one case to drinking large quantities of fluids, and in the other, to total abstinence from water for a given time.

For this reason, great physical exertion, causing loss of water to the system through increased action of the sudoriferous glands, provided a corresponding quantity of water is not taken into the system, will heighten the specific gravity of the urine. Wagner advises[3] in all cases where the specific gravity is lower than 1.010 or over 1.025, that careful inquiry be made into the amount of fluids taken into the system, and also into the quantity passed out through the medium of the sweat-glands. The quality and quantity of solids taken into the system also affect the specific gravity of the urine. Somewhat illustrative of this is the following: About two weeks ago I examined the urine of a patient in whom I suspected a disposition to nephrolithiasis, with the following result: The quantity of urine daily voided was not measured, but as near as I could learn was about normal, *i.e.*, about 1,500. Reaction was strongly acid; no albumen, no sugar. The sediment, microscopically examined, proved to be composed of urates in large quantities, some oxalates, and a few epithelia of the bladder or vagina; no casts, no blood; color, reddish-yellow; specific gravity, 1.030. Now, in this case, we have a high specific gravity, and if my only method for determining the presence or absence of sugar in urine had been a high or low specific gravity, respectively, I might very easily have overlooked one or two facts, and concluded that the presence of sugar must have been the cause of the high specific gravity in this case. On inquiry, I learned that my patient had been taking but little exercise, had been eating principally meat, and drinking but little for some time past. About ten days later, having prescribed nothing more than moderate exercise, together with a freer use of liquids and a smaller amount of albuminous food, the result of a second examination of the urine was as follows: Quantity about normal; reaction strongly acid; no albumen; no sugar; light, cloud-like sediment, composed of oxalates; a few epithelia of bladder or vagina, and some mucous corpuscles; no urates, no casts, no blood; color, light-yellow; specific gravity, 1.016. Now, whatever else may have had its effect, in this case neglect of a proper amount of exercise, together with the small quantity of fluids, and a diet composed principally of meat taken into the system, had an undoubted and marked influence on the specific gravity of the urine.

Temperature-changes have also an effect on the specific gravity of urine outside of the system, although for the practising physician they are perhaps of no value. Simon found[1] that urine which had a specific gravity at +12° C. of 1.021, had at +15° C. 1.020 and at +18° C. 1.019. Let us now glance for a moment at the specific gravity of urine in cases of Bright's disease. The limits within which the specific gravity of urine may vary in acute cases of Bright's disease are even farther apart than in health. Where the daily quantity of voided urine is less than in health, we find it averaging about 1.025, and in cases where the quantity is greater than in health, as low as 1.005. Wagner tells us[2] that in acute hemorrhagic morbus Brightii, and in those forms where but little albumen is present, the specific gravity averages 1.010; but in these cases where much albumen is present, and no hemorrhage, the specific gravity is mostly increased. He says further, Bartels found several times, at the commencement of the disease, 1.031, Bright and Frerichs 1.032; Gorup-Besanez 1.035, and Heller as high as 1.047. These figures show clearly how great is the range of the specific gravity in acute cases of Bright's disease; but as sugar is never present in uncomplicated cases of nephritis, and least of all would an error in diagnosis in this respect be made in acute attacks, we will go on to the consideration of the chronic form. In the early stages of chronic Bright's disease, he who considers a high specific gravity of urine as sufficient evidence of the presence of sugar, can, and would probably very often, err greatly in the diagnosis, for the specific gravity then is often between 1.020 and 1.030 and sometimes as high as 1.040 and even 1.044. It is true that the daily quantity of voided urine is, in such cases, less than in health, and sometimes very much less, and that albumen is usually present in large amount, but he who easily allows himself to be misled in regard to proper methods of examination may readily overlook much that is present, and see (?) much that is not present. In the later stages of chronic Bright's disease, and especially in those forms known as "waxy kidney," and "small granular kidney" the specific gravity is lower than in health, and consequently for the purposes of this paper does not need further consideration.

Let us now turn from those cases which show a high specific gravity of urine, but by the tests usually adopted in the clinics contain no sugar, to those in which sugar is easily proved to be present, and let us first consider a few cases of simple glycosuria before we turn our attention to diabetes mellitus. Von Frerichs, in his excellent work on diabetes[1] gives a table of cases of glycosuria, on pages 26 and 27, caused by poisoning by carbonic oxide gas. Of ten cases in which sugar was present in the urine, the average specific gravity was 1.023, the highest being 1.030 and the lowest 1.015. On page 31 of the same work an interesting case of attempted suicide by drinking concentrated sulphuric acid is described. The specific gravity of the urine, taken at ten different times, was as follows: 1.045, 1.039, 1.031, 1.030, 1.033, 1.034, 1.025, 1.023, 1.015, 1.010, and averaging 1.028. Although this case is described under the head of glycosuria, and notwithstanding the high specific gravity of the urine, no sugar (nor for that matter albumen) seems to have been present, but acetone and sulphuric acid were. Levinstein[2] after having administered 0.27 morphium to a rabbit, found sugar in the urine of the animal, taken from the bladder three hours after death, the specific gravity of which was 1.019. Von Frerichs, in his work already alluded to, describes a great many interesting cases, but for our purpose it will be sufficient simply to notice a few of them, especially in connection with a high or low specific gravity of urine. Thus on page 40, loc. cit., he describes the case of a hypochondriac: sugar in urine; specific gravity, 1.012 to 1.018. Page 53, aneurysma arteriæ cerebri profundæ sinistræ: neither sugar nor albumen; specific gravity, 1.026 to 1.028; sugar, 1.029; albumen; no sugar, 1.036. Page 56, loc. cit., apoplexy-aneurism: urine taken from bladder post-mortem; sugar, 1.013. Same page, apoplexy: urine also taken from bladder post-mortem; sugar and albumen, 1.011. Page 60, loc. cit., meningitis cerebro-spinalis: sugar and albumen; specific gravity, 1.012; sugar only, 1.011; sugar, 1.010. In several of the foregoing cases of glycosuria the specific gravity of the urine was so low that an examination with the urometer would have revealed nothing that could have led even to a suspicion of the presence of sugar. It is true that in some of these cases, as in many others, the knowledge of the presence of sugar in the urine would have had but little practical worth, and would have made but little or no difference in the plan of treatment. But there are many cases in which it is necessary to know whether sugar is present or absent in the urine, in order to make a correct diagnosis or to treat the case with any hope whatever of success, and it was to emphasize this well-known fact that they were chosen, for here such a means of examination could have given none other than a negative result.

Perhaps some of the following remarks on, and cases of, diabetes mellitus, will illustrate this more forcibly. In regard to the quantity, color, specific gravity, etc., of the urine of persons suffering from diabetes mellitus, v. Frerichs tells us[3] that the daily quantity of voided urine is sometimes normal, although generally exceeding that of health; that this quantity usually ranges between two and five litres, although he has seen cases where the amount was twelve and thirteen, and even as much as fourteen litres. But he says, this must be borne in mind, that this increase is by no means a necessary symptom of the disease, for there are severe cases of diabetes in which, even unto the lethal end, a noticeable increase of urine is never present. As the quantity of the urine increases, the color becomes lighter, paler, mostly playing into green, and sometimes as clear as water. Sediment is usually wanting, although urates and oxalates are sometimes present. After the urine has stood for some time a "whitish" sediment is formed in consequence of fermentation. The odor of the urine is sometimes peculiarly aromatic, its reaction almost always acid, and this acidity is present for a longer time after standing than in healthy urine, because of the fermentation. The specific gravity is almost always higher than in healthy urine, and ranges from 1.020 and 1.025, very often up to 1.030 and 1.040, and occasionally is as high as 1.050, and in a very few cases as high as 1.055; *but it must not be forgotten that there are cases of diabetes in which the urine shows a specific gravity of* 1.010. From all this, it seems to me, the fact must be patent to anyone knowing anything of medicine, that the specific gravity of urine may be so variable, even in diabetes mellitus, that it has little diagnostic value, and absolutely none as a means of determining the presence or absence of sugar. The case mentioned by the Vienna special correspondent of THE MEDICAL RECORD, in the letter already alluded to, serves to illustrate this admirably. The writer says: "The patient passed at present 1,300 to 1,500 grms. of urine in twenty-four hours, and in the entire history of the case the quantity of urine per diem had never been over the normal amount. The specific gravity averaged, for the past two months, 1.014, and at no time had it been above 1.025. The particular specimen of urine exhibited with the case had a specific gravity of 1.010, and contained thirteen per cent. of sugar," etc. In this case we have a very low specific gravity, and an unusually high percentage of sugar, and the urometer alone would have led to anything but a correct diagnosis.

Of many cases which v. Frerichs observed, I will simply call attention to a few. On page 145, loc. cit., are two cases recorded, in the urine of both of which sugar was found, and the specific gravity was 1.017 and 1.013 respectively. In another case sugar and albumen were present; specific gravity, 1.011. In still another (loc. cit., p. 147) sugar and albumen; specific gravity, 1.017. In another case (loc. cit., p. 204), on four different days the specific gravity of the urine of a diabetic patient was respectively 1.017, 1.010, 1.015, and 1.013; sugar present each time. On page 243, loc. cit., the specific gravity of urine, taken on several occasions, was as follows (sugar present each time): 1.012, 1.018.5, 1.011.5, 1.014.5, 1.015, 1.010.5, 1.014.5, 1.009, 1.014, 1.019, and 1.009.5

Flint records the following:[1] "Seven pints of urine were withdrawn from the bladder during the coma (the specific gravity, 1.015), and it was found to contain both sugar and albumen." These cases serve fully to illustrate the fact already mentioned, that sugar is not infrequently found in urine having a low specific gravity, and, therefore, a low specific gravity is no evidence of the absence of sugar. I have elsewhere endeavored to show that a high specific gravity is no evidence of the presence of sugar. If, therefore, a low specific gravity of urine is no evidence of the absence of sugar, and a high specific gravity is no evidence of the presence of sugar, then clearly the methods adopted to prove the presence or absence of sugar must be something other than those determining the specific gravity. I have here endeavored to show that all such methods as those referred to are not advisable, and the conclusion drawn from them cannot be relied on, although in one or two isolated cases they might chance to be correct. If this article should come to the notice of any practitioner who has fallen into the way of using the urometer as a means for diagnosticating the presence or absence of sugar in urine, I trust that it will convince him of the uselessness of such an examination, and lead him to seek out methods that are reliable and trustworthy.

CHARLES F. NORTH.

THE TREATMENT OF VOMITING IN PREGNANCY.

To the Editor of The Medical Record.

Sir: Apropos of the recent discussion of Dr. Wylie's paper on the treatment of the vomiting in pregnancy by dilating the cervix, I desire to furnish a small contribution to the subject by first referring to a case where this measure was employed but signally failed to relieve the symptoms.

Two years ago a patient in the third month of pregnancy had been attended by Dr. J. M. Pace, of this city, for intractable vomiting during a period of three weeks. A host of remedies had been tried, by mouth, rectum, and skin, including blisters to the epigastrium, but beyond a few hours of temporary relief no substantial benefit had been derived from their employment. When I was called in the case had already begun to assume a very serious aspect. The patient was a very delicate lady, of a highly nervous organization, and the innutrition and shock consequent upon the incessant vomiting had attenuated her to the last degree, and induced a condition of neurasthenia which was indeed painful to behold. Every particle of food and medicine was promptly rejected. The slightest exertion brought on syncope, and every symptom seemed to indicate a rapidly approaching fatality. Several days before my arrival Dr. Pace had, following the advice of Sims and Carl Braun, mopped over the cervix a solution of silver nitrate, and later had inserted his index-finger into the cervix up to the first joint, and beyond perhaps, but these procedures had made not the slightest impression on the hyperemesis.

With some misgiving as to whether the patient could at this stage bear an operation which might be followed by an abortion, I suggested that a more thorough dilatation be effected with a steel expanding dilator. The patient was accordingly placed in Sims' position, an Atlee dilator passed up to the internal os, and the cervical canal carefully but thoroughly dilated. No relief was afforded. The vomiting persisted as before. An abortion, no doubt superinduced by my interference, followed after three days, which severely taxed the flickering vitality of the patient, but bringing immediate relief to the vomiting. The patient recovered after a slow and painful convalescence from a pelvic cellulitis which supervened on the expulsion of the fœtus.

Is it justifiable to produce abortion in any case? Barnes unhesitatingly advised it. Tarnier would resort to it under some circumstances. On the other hand, Cazeaux earnestly opposed the suggestion and described a most remarkable case, related to him by P. Dubois, which had been abandoned by the latter and a colleague, and which afterward promptly recovered on the exhibition of a purgative. More recently Carl Braun, if I quote him correctly, emphatically condemns the practice.

If, therefore, we would follow the latter eminent authorities, and avoid the risks of an induced abortion, may not the dilating procedure of Dr. Wylie, which in many cases, it must be acknowledged, will excite uterine contraction, prove to be a Greek-bearing gift to the patient, already handicapped with an extreme degree of cardiac debility and nervous exhaustion?

It is true that the uterus will in some patients bear an amount of irritation which is truly astonishing. Witness the case, reported I believe by Dr. Mundé, where the cervix was amputated for an epithelioma in a pregnant female, who afterward made a trip to Europe, and, if I remember aright, was safely delivered. I have many times known the sound to be introduced into the cavity of the pregnant uterus and caustic applications carried up above the internal os and no uterine action be induced.

But do such cases indicate the rule? If not, *the rule* may be disregarded by experts, even in the absence of an emergency; but for the profession at large I am rather inclined to believe that Carl Braun's teaching, although too dogmatic, is the most conservative.

Moreover, I am induced to believe, by a close study of such cases, that while the emesis of pregnancy is a pure neurosis, of reflected origin it may be, it is the morbid expression of an individual nervous endowment which in many cases will not be amenable to any treatment, not even that of emptying the cavity of the uterus.

This view has been fully elaborated by Brock, who according to the anatomical and clinical facts critically examined the theory of Barnes advocated by Dr. Wylie, and that of Hewitt and of Bennett seriatim, and rejected them all as being unsatisfactory. It will be remembered also as corroborating Brock's opinion, that, in some cases, although the uterus has been rid of its contents, the vomiting persists, or recurs after a remission, and ultimately proves fatal. Tarnier and others relate such cases, and it is evident that in all such the widest dilatation of the cervix effected by the passage of the womb contents has not removed the cause of the emesis.

However, we must admit that in extreme cases of hyperemesis the question of induced abortion may be legitimately considered and settled according to the individual judgment of the skilful and conscientious practitioner, reinforced by the concurring opinion of a worthy colleague.

Yours respectfully,
Henry K. Leake, M.D.

Dallas, Tex., December 10, 1884.

OUR LONDON LETTER.

(From our Special Correspondent.)

KLEIN ON THE COMMA BACILLUS AND ITS RELATION TO CHOLERA—DENTAL EDUCATION AND PRACTICE IN ENGLAND—A VISIT TO THE DENTAL HOSPITAL.

London, February 7, 1885.

An interesting and important paper has just been read before the Royal Society by Dr. Klein on the subject of the relation of the comma-shaped bacilli to Asiatic cholera. Your readers may remember that Dr. Klein, with two other medical men, was sent out to India last year to investigate the question of cholera and its etiology. In his recent paper before the Royal Society he gives the most important of the conclusions arrived at by himself and his colleagues on the British Cholera Commission. These differ in many important respects from the results arrived at by Dr. Koch and the German Cholera Commission.

The English Commission agree with Koch as to the constant occurrence of comma bacilli in the rice-water stools, but remark that they differ greatly in number in different cases. They also found them in the mucus-flakes of the rice-water stools and those taken from the ileum of a cholera patient after death. But whereas the German Cholera Commission found the comma bacilli in the lower part of the ileum of persons dead in the acute stage in such numbers that they regarded that region as containing "almost a pure cultivation," Dr. Klein maintains that the sooner after death the body be examined the fewer comma bacilli will be found in the mucus-flake, and that in typical cases ending quickly in death the mucous membrane of the ileum will not be found to contain in any part any trace of a comma bacillus or any other bacteria, not even in the superficial loosened epithelium. If the post-mortem be sufficiently delayed, comma-bacilli and other bacteria may be found penetrating into the spaces of the mucous membrane. Dr. Klein and his colleagues do not, therefore, agree with Koch in considering the lower part of the ileum as the site of a pure cultivation of comma bacilli, and do not accept his theory that the comma bacilli present in the mucous membrane secrete a chemical poison. Koch considers the comma bacillus to be specific, and not only important diagnostically, but the true cause of cholera. Klein remarks that the behavior of the bacillus in different media is not such as to justify us in viewing it as "specific."

Comma bacilli occur in other intestinal diseases. Dr. Timothy Lewis, Assistant Professor of Pathology at the Army Medical School, Netley, has found them repeatedly in the mouths of healthy persons. I referred to Dr. Lewis' researches in a recent letter. Their importance was at first questioned on the ground that Dr. Lewis had performed no cultivation experiments with these comma-shaped bacilli. It has, however, since been shown that they display the same peculiar characters of growth in gelatine as Koch's comma bacilli from cholera cases. Dr. Deneke has also found comma bacilli in some articles of food, as stale cheese.

On these and other grounds, Dr. Klein and his colleagues, Dr. Heneage Gibbes and Mr. Alfred Lingard, deny the importance and specificity of the comma bacillus, and maintain that the experiments on animals by Koch and others do not in the least prove that the comma bacilli are capable of producing cholera or any other disease. They observe that, in the case of the tanks near Jelepara Lane, there is direct evidence that water contaminated with cholera evacuations (and therefore containing comma bacilli) did not cause cholera when used for drinking and all domestic purposes by a large number of persons. This is in accord with the views of a large section of Indian medical men, to which I referred on a previous occasion.

Dental education is looking up in England. The Dental Act passed a few years since, although it admitted to the Dental Register a horde of ignorant persons on the (in many cases very flimsy) plea of previous practice as recognized, although unqualified dentists, is likely to bear good fruit in the future. It is now distinctly laid down that no one can legally practice dentistry without the possession of a dental diploma. (This, of course, does not apply to medical men, whom it is not intended to exclude.) To obtain this, mechanical dentistry must be studied for a period of not less than three years under a competent practitioner, a dental hospital be attended for two years, and a rigid examination passed. I am speaking of the requirements for the London Dental Society, England.

A recent visit to the large building in Leicester Square, known as the Dental Hospital of London, has convinced me that if English students do not become competent dental practitioners it is not from any want of training. Under the auspices of the courteous dean, Mr. Morton Smale, I made the tour of the building. The room for extraction is on the ground floor, and gas is given in all cases where it is considered desirable. Nitrous oxide is here given more frequently than probably at any other hospital in London, and no care is spared in its administration. To this may probably be attributed the long roll of cases without a death, which is probably unequalled elsewhere. The stopping room is at the top of the house, and on entering it a strange spectacle is seen. The large room—nearly sixty feet long by about twenty in width—is literally full of dental chairs, in each of which a patient is reclining for operative purposes. Either the patients are afraid to give any audible sign of pain, or the operators are so skilful as to give very little, for during my stay of nearly half an hour I heard no sound other than the click of instruments, the whirr of dental engines, and the subdued hum of conversation as the surgeons and demonstrators passed from pupil to pupil to instruct them how to proceed. The museum is quite worthy of being inspected, as it contains many interesting specimens, the counterparts of some of which are certainly not to be found in other museums. The Dental Hospital is well worthy of a visit from Americans in Europe, whether physicians or dentists, and they will find the staff only too happy to afford them every facility for inspecting the institution and its practical working.

American dentistry has, I am aware, acquired considerable repute both in America and Europe, but I have said enough to show that in London, also, we are doing our best to advance dental science and practice.

OUR VIENNA LETTER.

(From our Special Correspondent.)

A CASE OF DEATH DURING CHLOROFORM NARCOSIS—BILLROTH'S GASTROTOMIES—PROFESSOR KAPOSI ON SYPHILIS—THE BACILLUS OF SYPHILIS.

VIENNA, February 3, 1885.

THE following case of death during anæsthesia occurred last week. The patient was a man forty-eight years of age, who had received a compound fracture of both bones of the leg just above the ankle. The fracture was put up in a plaster-of-Paris splint immediately after the accident. A few strips of iodoform gauze only were between the leg and the plaster splint. Three days later the man was brought into the hospital with extensive and deep-seated phlegmonous inflammation about the injury. Extensive incisions were made and a drainage-tube inserted, and the leg redressed under antiseptics by Professor Billroth.

But, notwithstanding, symptoms of septicæmia set in, and the parts became gangrenous. The leg was then amputated two days later at the junction of the lower and middle third of the thigh, the operation taking place on Saturday, when Professor Billroth does not hold a clinic; only the assistants and a few of the members of a private course of Dr. Hacker, the first assistant, were present. The operation was made by one of the assistants. The patient took the anæsthetic very well, and the first indication of anything wrong was that on the removal of the tourniquet no bleeding took place from the stump; the end of the femoral artery was seen pulsating feebly. The radial pulse was almost imperceptible, the breathing short and slow, but not shallow. The anæsthetic was at once removed, and electricity, sulphuric ether injections, and other stimulants applied, but the heart's action, which was very weak, became feebler, and the patient died at 1.30 P.M., two hours after the beginning of the operation. The respiration continued for nearly half an hour after the heart had apparently ceased to beat. The length of time, from the time the patient was fully narcotized till the removal of the tourniquet, was fifty minutes. The patient was a drinker, had emphysema of the lungs, and atheroma. The anæsthetic used was the so-called "Billroth's mixture," and consists of chloroform, 200 parts, sulphuric ether and alcohol, 60 parts each. About three ounces of the mixture was used in this case.

Professor Billroth was not present at the operation, which took place on January 24th, and by some error the case was reported to the students as having died of shock during the night after the amputation.

Professor Billroth, by a stomach resection in the latter part of January, brought the number of his gastrotomies to eighteen. In this last case a carcinomatous tumor, the size of an orange, was removed from the stomach, and since the operation the patient has done well, without a rise of temperature; has taken liquid food by the stomach since immediately after the operation, lately small amounts of solid food, and will soon be considered as entirely cured. Dr. Hacker will soon publish in pamphlet form a full account of all of Professor Billroth's stomach resections, with the immediate and ultimate result of each case.

Professor Kaposi, the professor of skin diseases in the Vienna University, is probably the best known advocate of the theory of the unism of syphilis. In some of his latest lectures he has made a most clear and forcible statement of his views, which are entirely opposed to those held by his contemporaries. He denies that the distinction between hard chancre and soft chancre, or chancroid so called, as to one being followed by general symptoms and the other not, can be made. Both are equally syphilis, and either or neither may be followed at a later period by general symptoms. A patient may have a typical hard chancre and after it have no constitutional symptoms. Patients, where the induration of

the sore was unmistakable, had been kept under observation in the hospital and outside of it for from several months to over a year, and in this time had had no secondary symptoms whatever. On the other hand, Professor Kaposi had in his practice repeatedly cases of soft chancre which later had gone through all the forms of secondary syphilis. In these cases the utmost care and pains were taken to find an induration, if present, but none was discovered. Still further, the professor went on to state that the initial lesion of syphilis, though usually an ulceration or an open sore, was not necessarily or always so. It might be a condyloma, or in other cases the initial lesion was not to be discovered by any external or local appearance. In view of these facts, which he had verified over and over again by the most careful and exact observation of patients, Professor Kaposi divides syphilis into two varieties: 1, *idiopathic*, where the disease goes no further than the local affection, which may be either a hard chancre, a soft chancre, or neither; and 2, *symptomatic syphilis*, with a similar initial lesion but followed by secondary constitutional symptoms. As to treatment of this disease, the Vienna method is about the same whether one is a dualist or an unicist. The local initial lesion, if with induration and on a tissue which can be so treated, is immediately excised. If a soft sore, or if it is located where it cannot be cut out conveniently, as on the glans penis, it is treated simply with emplast. hydraryg, this being now almost the only local application to soft and hard chancres at present in use by Vienna surgeons If secondary symptoms develop, hypodermic injections of a mercurial salt, usually the protodide, are used throughout the course of treatment. The injections are given in the cellular tissue of the back, on each side of the spinous processes. The syphilis bacillus which Dr. Lustgarten thought he had discovered, is thought by most of the Vienna syphilographers not to be the syphilis bacillus at all. Professor Neuman is outspoken in this belief, and says if there is a syphilis bacillus, it is still to be discovered. Other authorities here are less frank, but say that it is very difficult to distinguish this bacillus from a tubercle bacillus.

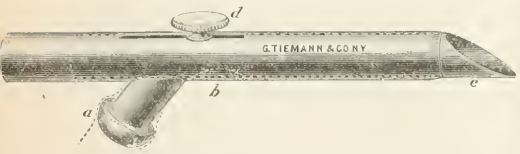
New Instruments.

A NEW AND SIMPLE OVARIOTOMY TROCAR AND CANULA.

By EDWARD S. DUNSTER, M.D.,

ANN ARBOR, MICH.

With a view of obtaining a less complicated as well as a less expensive ovarian trocar and canula, than the well-known and excellent instruments of Sir Spencer Wells and the "Fitch dome," I suggested to Mr. Stohlmann (senior partner of the house of George Tiemann & Co.),



to make for me the instrument illustrated in the accompanying wood-cut engraving. The drawing (which is half size) shows so clearly what the instrument is, that no elaborate description of it is necessary. It consists simply of two concentric and accurately adjusted tubes, one sliding within the other, thus making a canula and trochar proper. The canula (*c*) is adjusted by the set-screw (*d*), and has in it a fenestrum shown in dotted lines at *b*. When the cutting point of the canula is withdrawn into the trocar, this fenestrum comes directly opposite the outlet tube (*a*), to which rubber tubing, at convenience, is to be attached. The instrument, in using, is held in one hand just like a pistol; the proximal end of it, which is capped with a solid convex plate, is placed in the hollow of the hand; the middle, ring, and little fingers grasp it in front of the outlet (*a*), while the thumb and index-finger are free to fix or move the canula forward or backward as required by means of the set-screw (*d*). When the cutting point (*c*) is withdrawn into the trochar, there is no sharp edge or point which can damage the tissues into which it may be introduced.

The special advantages claimed for the instrument are: 1, it can be held and used with one hand alone, leaving the other hand free for the operator to use as may be required, while the grasp (pistol-fashion) is so firm that the instrument is under perfect control; 2, the construction is so simple that the instrument can be cleaned and kept clean with ease; in these days of antiseptic surgery this feature in an instrument is an important consideration. By removing the inner from the outer tube every portion of both inner and outer surfaces of the instrument can be easily reached with a carbolized cotton swab, and there are no sharp angles, corners, or crevices in which septic matter can lurk to do its deadly work by being carried into the tissues in operating; 3, it is, or ought to be, furnished at much less expense than either the Spencer Wells or the Fitch dome.

The instrument is nickel-plated and burnished inside and out. I have used it in several ovariotomies and it works with perfect satisfaction. I would suggest that if made of various smaller sizes and lengths it will be found an excellent and handy substitute for the trocars in use in general surgery.

University of Michigan, February 7, 1885.

A VAGINAL DOUCHE.

By L. A. FROST, M.D.,

JACKSONVILLE, ILL.

This vaginal douche is intended to be a convenient and efficient instrument for administering the prolonged hot-water douche as recommended by Dr. T. A. Emmet, of New York.

It will be seen to consist of two portions; the nozzle, joined to a rubber tube, which passes through the shield portion, and through which the injection is to flow. Also a bulbous part, which is introduced into the vagina as far as the rim will allow, and which by its shape is calculated to be self-retaining, and also to act as a plug so as to cause the vagina to be filled with water.

As soon as the vagina is filled, the surplus passes off easily through the hollow bulb, and out through the rubber overflow tube, into a receptacle placed beside the bed for its reception.

Having a large pitcher on a stand at the bedside, filled with water at the proper temperature (say 110° F.), and a Davidson's syringe tied to the handle of the pitcher so as to prevent its slipping out, the nozzle of the syringe is introduced into the short tube, and the stream started, at which time the instrument, previously oiled, is to be introduced into the vagina. It can be used by the patient without an assistant if she so desires. As the bulbous portion plugs the vagina efficiently, it can be used without danger of wetting the bed. It will be found to be equally convenient with the patient lying either in the knee-chest position, or upon the back.

CHOLERA AS REGARDS QUARANTINE, AND ITS PREVENTION, PATHOLOGY, AND TREATMENT.

BY MONTROSE A. PALLEN, A.M., M.D., LL.D.,

NEW YORK.

THE geographical history of the progress and appearance of cholera since 1848 is too well known for repetition. A large number of the profession are personally familiar with the havocs of the disease, and its self-limited stay in the various parts of Europe and America. From 1873 until 1884, the fears of a reappearance of cholera in Europe and America have been at a minimum, because of the supposed perfection of quarantine and disinfection.

It was believed that certain materials, such as chlorine, carbolic acid, and all that class of so-called germicides, were quite sufficient to destroy the cholera poison, whether it existed in the form of microbe (Dr. Koch), or whether it was bacillus, as believed by many of the materialistic microscopical school of modern pathologists. Unfortunately, after the lull and repose that this belief begot, cholera suddenly uprose in 1883, from the torrid and filthy towns and cities in Egypt, and for a few months ravaged Alexandria, Damietta, Cairo, and other places of less importance. The believers in the "portability theory," and in the "absolute protection" by quarantine, sang pæans of gratitude when, after a couple of hundred days, the pestilence was declared to be stamped out of Egypt, and that Europe was freed by the all-powerful quarantine and the use of germicides! Once more the repose of security and the confidence begotten of this all-powerful quarantine was broken, and like an alarm-bell in the darkest hour of the night, the dread sounds from Toulon in the early summer of last year awoke Europe and America from their dreams of safety. At first the quarantine protectionists declared it was simply an importation from Tonquin, by the troop-ship Sarthe, and that a few days of fumigation and quarantine would stamp it out, and once more they could proclaim themselves triumphant victors, who held within their hands the power to which disease was to succumb! But like Banquo's ghost it would not down. Day after day the pestilence increased, and within a few weeks it had reared its ghastly features in Marseilles, and the black war of death went on in spite of fumigation, disinfection, and the boasted capacities of quarantine to put it down. "Surely," said they, "quarantine must be defective; something is wrong." The French Government was appealed to, methods severe and harsh were demanded to keep it out of Europe. On the Italian frontier at Vintimiglia, the military were called out and regiments of carabineers threatened to shoot those hapless fugitives from French soil who dared to invade the Italian Riviera.

The public press, at the dictation of popular sentiment, almost without exception, called upon the French Government to interdict communication, to keep the inhabitants of those districts confined within the limits of the diseased area; but, fortunately for the name of humanity, the Academy of Medicine in Paris declared that they saw no reason why such energetic and decided measures should be adopted; that cholera could not be kept out, and it was unwise and inhuman to subject the inhabitants of the unfortunate cholera-smitten districts to detention as prisoners.

I was a looker-on during this popular frenzy, when the entire community seemed to be under no control or restraint, when fear seemed to madden whole cities, and when one was led to believe that cholera, like a great black wave, was being rolled over all France to destroy and annihilate. The calm, cool, and wise action of the French Academy of Medicine has proved that cholera cannot be stayed or limited, and the severe and harsh measures of the Italian authorities have enabled us to reply to the utter inefficiency of even a military cordon. Naples wails like Rachel, because her children are not. The heroism of the Italian King likewise demonstrates that as yet Rome has not been afflicted with "portable cholera" in consequence of his grand and sublime visitations to the afflicted Neapolitans. I do not wish to be considered a believer in the disestablishment of quarantine. On the contrary, I am quite satisfied that it is an adjuvant, and a most powerful one, to regulate the importation of contagious diseases proper, such as small-pox, yellow fever, and others of that class, but that it will keep out cholera has thus far, to my manner of thinking, been proved quite inefficient, and it is a delusion and a snare for us to trust entirely to such sentinels on the outposts, who are placed simply to give warning of the approach of the enemy.

The objection to quarantine is that public sentiment has been educated into the belief that its efficacy is so great as to actually prevent the inroads of all diseases, but public sentiment must discriminate between contagious diseases proper and the infectious. Not for one single instant would I abate one jot or tittle in the strong discipline of quarantine, but it must not and should not be our only sentinel. Cholera feeds upon certain conditions, certain continued influences, developed by the aggregations of people, the accumulations of filth, and the refuse of crowds, together with certain fermentations produced by sewage, heat, moisture, atmospheric states, and other causes that the scientific world has not yet determined.

The way to prevent cholera is to get rid of these causes; not to let the soil with such tendencies to fructification be over-ripe when the poison is deposited. Quarantine may do very well to prevent the dissemination of this disease, if there be no place whereon it can be lodged and germinated. And this lodgment will fail to reach any maturity when the conditions to its ripening are removed by proper cleanliness and common-sense hygiene. It is a fact beyond dispute, as witnessed in numerous instances, that the material of which cholera is developed may be scanty at one time—not sufficient to disseminate itself over an entire country—and by the law of self-limitation, is soon expended and overcome. However, this spot having once shown a tendency, from the union of all the conditions, for the development of cholera, may, later on, when the poison has spread more energetically and in greater quantities, determine an epidemic of the most malignant and fatal character.

It is useless to cite all the facts as to the appearance and disappearance of cholera preceding and subsequent to great epidemics, which cannot be explained on the grounds of human portability. If we are to believe Dr. Koch and his enthusiastic admirers, the only possible way to be affected with cholera is in the swallowing of the terrible microbe. But just at this very time the news

comes from Paris that Dr. Briard, and from Calcutta that Dr. Klein, had the audacity to mix up in their drink the microbes of Dr. Koch and swallow them, and both gentlemen are alive to tell the story and refute the theory. No one will deny that good diet, proper clothing, freedom from excess, regular habits, and a well-ventilated residence reduce the tendency to the development of cholera to a minimum. But all these conditions invariably put people in the best possible condition of health, and give them a power to resist the onslaught of any disease whatever. For that reason, medical men seem to be less prone to the affliction of all disease, because they are so much in the open air, because they usually live in a prudent and temperate way, and are generally well fed, well clothed, and well housed, and, therefore, in the best condition to resist the destructive influence of any germ or poison, whether it be microbe or bacillus, that is thrown off by disease.

The inference, then, is that the highest standard of health, produced by the best possible hygiene, will do more to mitigate the severity of an epidemic, when it does come, or in a measure to prevent its outbreak, than any specific fumigation, medication, or quarantine. Every one is well aware of the fact that the refuse and filth of a large town, or the imperfect drainage and badly constructed houses or hamlets in villages and small towns, are the great factors in the development of any disease. Witness, for instance, the fearful epidemics of the plague which have almost destroyed the populace of Constantinople, Smyrna, and Cairo time and again. London itself was almost depopulated until its great fire burnt out the plague-spots, and since the rebuilding there has been no plague in that city. Good houses, better paved streets, and good sewerage have removed all elements of the plague. Again, the history of typhus fever proves that it is the outbreak of overcrowding, of bad and insufficient feeding, and poor ventilation; a pestilence of typhus ought to be an anomaly now, and is a criminal neglect in a well-organized community. Quarantine could easily beat back an invasion of such contagions as typhus, the plague, small-pox, scarlet fever, and possibly diphtheria, because they are all of them clearly traceable to filth, sewage, and absolute bodily empoisonment. But this does not obtain with cholera. Follow any epidemic whatever, and it will be seen that certain conditions, hitherto undiscovered by scientific research, constitute in a great measure the factors in the development of the disease. That cholera poison resides in, or is absolutely carried by, the winds is very questionable, because it has been known to travel from Jessore to Calcutta in the very teeth of a southwest monsoon; it has crossed mountains and has overcome all barriers; but these facts do not prove that there are conditions, electric, cosmic, and telluric, combined with moisture and fermentation, which invade and percolate an entire district or even continent. In proof of this fact, I have witnessed, time and again, and it was an observation generally made by all persons in the Mississippi Valley, that the drinking-water of the Mississippi River, prior to and pending the very severe epidemic of 1866–67, was absolutely so stinking, after having remained for an hour or two in a pitcher, that no one could drink it. At St. Louis, where I observed this most frequently, the water was collected several miles above the city, where the current was running at least four or five miles an hour, and a few miles below where the Mississippi and Missouri rivers unite, and the combined waters flowed from a distance of 5,000 miles! This Mississippi water at New Orleans, 1,000 miles below St. Louis, in the times when sailing vessels were very numerous, was always put in the drinking casks of ships, even such as were expected to make a return voyage, because it kept pure from New Orleans to Liverpool and back. Here was a condition totally inexplicable, but nevertheless it was a coincidence with the cholera, and even prior to it; and the purest of drinking-waters, because of the alluvial clays mixed in it, became fetid and unfit for use. Yet ninety-nine hundredths of the people of St. Louis drank this water, and no one would pretend to believe that the stinking condition was the result of the deposit of the microbe at the head-waters of the Mississippi and Missouri, where the cholera did not exist, but that it was developed from some cause unknown, and coincided with the spread of the cholera epidemic.

Many theories have been advanced with regard to the cause of the cholera. We know the conditions which constantly exist in its birthplace—in the Delta of the Ganges—filth from the accumulation of large crowds of people, poor food, exposure to great vicissitudes of temperature, and the general impoverished state of the lower classes, who inhabit and visit it. Now, whether this disease is developed purely and simply in consequence of the crowding of such masses of humanity and the accumulation of such filth is a question not yet absolutely determined. Certain it is that the cholera is always found at that point, and certain it is, also, that, notwithstanding the elements in the production of the disease constantly existing there, it is not always an epidemic that propagates itself beyond the confines of the Delta of the Ganges.

The only rational deduction there is in the explanation of an epidemic of cholera which can be given, is by a union of this plus-condition, vicissitudes of temperature and the filth accumulating from the aggregation of a great number of people. It is this plus-condition which makes the disease epidemic, and develops the cholera wave; and this epidemic, when stimulated to such an intensity as to make it an epidemic proper, has the plus-condition amalgamated with it, and overrides all efforts of quarantine to keep it out of communities. When it finds a soil, such as is to be found in the city of New York at the present time, it makes desolation and havoc among its inhabitants.

It is a mistake for us to rest under the belief that if cholera were to invade New York, it would be slight, transitory, and easily controlled; *provided, however, that we got the disease in such intensity as was developed in Toulon, Marseilles, or Naples*, within the past year. It is true, however, that if a cholera wave were slight and mild, and therefore of little or weak intensity, its self-limitation might be feeble and of short duration, like corn planted on sandy soil, which would not ripen to the ear; but if it should come in the rich luxuriance which the plus-condition sometimes develops, and has hitherto developed in many instances, both in Europe and America, it might find a soil in the city of New York that would give forth a crop, rank, large, destructive, and taxing all our energies to counteract and control.

There can be no possibility of a doubt of the greater or less intensity of the cholera wave, and just in proportion to this intensity is the limitation of the disease; because, if this disease were not self-limited and did not die out in consequence of the destruction of that plus-condition, cholera would be perpetual, particularly if there is any truth in the theory that it is a purely portable disease, and is communicated in some way from one patient to another, in consequence of the presence of microbes or bacilli. Now, if we are to believe the delusive idea of the absolute safety in quarantine, and the correctness of the theory of portability, there is nothing under the sun which could keep the human race from being constantly afflicted with cholera.

The question arises, What is this "plus-condition"? What is the element that makes cholera an epidemic; that lets it settle down over an entire nation and abide with it for one, two, or three years, and then totally disappear for ten, a dozen, or twenty years?

Now comes the question, if we recognize the fact beyond the microbe and bacillus, that *there is a union of heat, and moisture, and filth, and sewage, and that "plus-condition"* for the development of the disease, what is the best way to prevent its germination and fructification?

We cannot sit as Canute did, and let the tide overwhelm us in the boastful power of a quarantine kingship, but we must remove ourselves from the surging waves or else be destroyed. Let us get rid of the recognized elements of cholera formation by destroying them; let us bend all energies toward the removal of every factor in the development of the disease by an enlightened hygiene, dictated by an experience begotten of the failure of quarantine, which has hitherto been powerless to stay the pestilence from invading both Europe and America.

There is but one solution to this problem—it consists in purifying and cleansing the city. But the question will arise, How cleanse the city? If we are to await action and appropriation from the Common Council and the Board of Apportionment, it will never be done. Or if these appropriations were made, the sum never would be large enough to have them properly carried out. The peculiar organization of our politics is such, that there never was, within the memory of the oldest inhabitant, enough money appropriated to do a piece of work according to the estimate. Jobbery and rings have prevented it, will prevent it; and, therefore, if we await the ordinary red-tape of civic subsidy, we will await in vain. It was very liberal in the American minister at Rome to give $5,000 to help the needy and suffering Neapolitans; but if they themselves had appropriated that sum, before the development of the cholera epidemic, they would possibly not have needed this generous donation from the representative of our Government.

There is but one certain way to have our city properly cleaned, and that is for the wealthy men of New York to raise the money and do it. Their interests lie in keeping this great metropolis free of epidemics, and their humanity ought to awaken a generous disposition to save the city from pestilential invasion, and their duty is, just as in the time of war, to arise and take arms against that which they alone can overcome and master. What if it costs a million dollars to properly clean the city and keep it so? Could there be a better investment? Just in proportion as epidemics are kept from the city of New York, so the value of property will be maintained and enhanced. Situated as the city of New York is, along a narrow strip of land, between two broad rivers, its borders washed by the tides, its death-rate ought to be the smallest of any on the habitable globe, and it would be the healthiest on the continent of America, if it were kept properly cleaned and freed from the accumulation of filth, the emanations of sewage and sewer-gases, and overcrowding in tenement-houses. It may be asked, How can this be done? Simply enough. Let there be erected in the east and west boundaries of the city, and at the end of such great thoroughfares as Wall, Cortlandt, Canal, Grand, Eighth, Fourteenth, Twenty-third, Thirty-fourth, Forty-second, Fifty-seventh Streets, etc., all the way up to Spuyten-Duyvel Creek, great pumps, capable of discharging hundreds of thousands of gallons of water within an hour, and when the tide is at its ebb, and when the sewers are empty of fluids, let them be washed out regularly every twenty-four hours, so that when the tide is flood again, and the water backs up into the sewers, it will not force up to the centres, the detritus and debris of sewage, and push the emanations into our streets, and into our houses the microbes, bacilli, and fermentative poisons, which beget not only cholera, but diphtheria, scarlet fever, pneumonia, typhoid, and typhus. There can be no other possible way of cleaning this city.

Our nostrils are almost hourly offended by the sickening odors of the street-cleaning carts, which back up in front of our houses to remove the garbage and ashes; and not only are our nostrils offended, but our eyes befouled with dust, and our lungs filled with unhealthy vapors. If, in addition to these direct conditions, we are constantly inhaling the noxious exhalations from the sewers, we would stand but little chance to resist the cholera poison, whether it be brought into the country by means of people or by ships. Certain it is, all the disinfection made by the quarantine authorities would be of little service if a cholera germ were let loose to feed upon the emanations arising from the accumulation of filth in certain quarters of New York City, in addition to the fermentative poisons issuing from our sewers. And just here I wish to interpolate a subject of great importance, especially pertinent at the present time. Talk with any of our ship-owners, or with the masters of vessels coming into the port, and the descriptions they give of the fumigations of their ships, coming from suspected ports, is actually farcical on the part of the quarantine officials; and they further say, that the burning of sulphur, or tar, or the exhibition of chlorine gas, or any other disinfectant or fumigator used, is not of the least possible service in the destruction of any germ or any poison of any disease whatever; it does not even kill the roaches or the rats found on board of every ship.

The only person benefited by such fumigation or disinfection is the recipient of the fee therefor.

Six times within the past four years have I been a witness to quarantine examinations at this port, and of that six times three times have I lain all night at Quarantine, and waited the arrival of the Health Officer at six o'clock in the morning, who received the report of the ship's surgeon; and the Quarantine Physician was perhaps ten minutes on board investigating and inspecting the ship! A gentleman interested in one of the steamship lines leaving this port for the Gulf of Mexico, who knows the construction of a ship thoroughly, tells me that both here and at New Orleans the fumigation of ships, for the purpose of cleansing them of yellow fever, small-pox, or any other poison, is simply absurd. To use his own words: "There are thousands of places in a ship that are never touched by the fumigating material or disinfectant, where the air is confined, and where, if there were any disease whatever, it would be sure to be concealed and pent up;" and that "quarantine as exhibited on the coast from Boston to New Orleans is utterly inefficient, and the effort to keep out diseases by disinfecting the shipping is a one-sided affair to total neglect of inland communication." It will thus be seen that if we ever should succeed in protecting the port of New York by a rigid seaward quarantine, and if the theory of human portability is correct, any individual may easily evade the seaboard quarantine and enter the city of New York, having come from a cholera-infected district or ship, and propagate the disease and develop an epidemic. Therefore let us free the city of any materials upon which cholera can feed; let us have the soil so arid and sandy, when the cholera wave comes, that its seed will not germinate and ripen.

Possibly these words of mine may not be heeded, and I may be looked upon as an alarmist. Most people who portend evil are called "croakers," but there is an old adage, one inculcated by Washington himself, that "in time of peace we should prepare for war."

The experience of Egypt in 1883, the horrors of Toulon, Marseilles, and Naples in 1884, all point unerringly to the handwriting upon the wall, unless all experience in the march and development of the epidemic since 1832 to 1873 be of no importance and productive of no lessons. Should cholera make its appearance here, we would witness bonfires lighted in the streets by day and by night, as was done in Marseilles and Toulon, and we would see the streets sprinkled with carbolic acid, as was done in those places, and in Paris. A terrible panic would seize upon the people; and those who could get away would, in the first days after the disease was declared epidemic, fly out of the city in terrorized hordes, as was witnessed within the last year in France and Italy. A pall would settle upon the community, blighting it, certainly for the time being, financially, socially, and politically. Is it not better, then, even at the expense of being considered over-cautious, even at the idea of being ridiculous, even in the hope that we may be wrong in so doing—is it not better, then, for us to do all we can toward cleaning and purifying and getting rid of

filth, sewage, and all the acknowledged factors in the production of cholera? I suggest the washing of the sewers by means of pumps, because it is so simple; and with such facilities as New York presents through its geographical position, it will be seen to be the simplest and surest way of purifying it. If there are other methods more effective, cheaper, and better, I am perfectly willing to see them adopted. We cannot expect the Board of Health, or any other organization directly or indirectly connected with the Street-Cleaning Department to even keep New York clean with the amount of money appropriated for that purpose. If we do so, we are laboring under that "hope deferred which maketh the heart sick." The people themselves must take this thing in hand. We cannot tell at what day a ship, landing from Italian shores, notwithstanding she may have a clean bill of health, notwithstanding she may have undergone a rigid quarantine inspection at the port of New York—and particularly if the human portability theory be correct—we cannot tell at what hour or what day, from that ship, the cholera will develop itself in the city of New York. The optimists of the community will say that, when cholera makes its appearance, it is only a sporadic case or cases. The quarantine protectionists will say that it can be beaten back; but the history of the past half century demonstrates that nothing has ever yet kept out the cholera after it has once taken a foothold in a community. Its severity has been mitigated by cleanliness of person and city, and in no other way, although Dr. Koch would make us believe that drinking water in which there are no microbes is a guarantee against cholera, and many so-called facts are quoted to sustain such an opinion. The stinking Mississippi of 1866 and 1867 settles beyond all question, in my mind, when the cholera poison is active, when the cholera wave is general, that thousands of miles of flowing pure drinkable water may be saturated with something besides microbes, to such a degree as to render it nauseous as to taste and disgusting as to smell.

The next question presenting itself for consideration is the treatment of cholera, when it does make its appearance. The literature of the subject, the experience of the profession, and the results obtained have heretofore not been satisfactory as to medication proper after the patient is once stricken down with the disease. Given a case of cholera, and the vast majority of individuals seen by medical men in an epidemic are already stricken with the pestilence—given a case, I say, can any man point to any forms or methods of treatment that have been of any certain avail to check the disease? If we consider the etiology and pathology of cholera, we would not think of introducing medicines into a stomach which not only will not hold the drugs, but even ejects the mucus and watery transudation constantly poured into its cavity from the lining membrane. The cholera stools likewise indicate that there is issuing through the walls of the intestinal canal not only the increased secretions of the mucous membrane, but likewise the serum of the blood. It is not probable, nay, it is not possible, that these vomitings and purgations, which are so prominent among the symptoms of cholera, should be the result of any special irritation in the stomach or intestinal tract. The dead-house has as yet not revealed to the pathological anatomist a sufficient cause to demonstrate any local gastric or intestinal cause.

We know what is not cholera, as far as any absolute results have been obtained; but we may surmise, and almost correctly, that the cause of cholera dejections and vomiting is in a paralysis of the vaso-motor system, and that the serum of the blood transudes the mucous membrane of the stomach and the intestinal tract in consequence of there meeting with the least resistance. In the examination of many of those dead with cholera, I have frequently found in the stomach medicaments administered to them during the period of collapse (after the vomiting had ceased) in the vain hopes that their absorption might stimulate to a reaction. Time and again have I witnessed the vomiting in cholera patients of everything administered by the mouth that went in the stomach, whether in the shape of water, stimulants, ice, food, or medicine. Under these circumstances it shows how almost futile is the task of the physician who hopes to effectually battle with the disease by the ordinary means of administering medicine by the stomach, and equally hopeless is the injection per rectum. There remains but one way of direct medication, namely, by hypodermic injection of such materials as may have an antidotal effect upon the poison which produces the paralysis of the vaso-motor system. Physiological chemistry has not as yet given us any absolute medication for this purpose, but the experience of clinical medicine teaches us that if we can get to a patient before this vaso-motor system is completely paralyzed we may sustain the heart's action by another paralysis of its so-called inhibitory (or check) nerves, and this is done by means of atropine.

Whether the theory of nerve inhibition is a physiological fact or not, as far as the heart is concerned, certain it is that the use of atropine seems to ward off any influence which would tend to weaken the heart's action. Again, atropine is said to producte a contraction of the muscular fibres between the elastic layers of the arteries, as well as the external muscular layers of the capillaries. It is an established fact that the maintenance of the elasticity and contraction of the arteries is a necessary condition for the proper circulation of blood through the tissues, and it is equally well known that the veins are endowed with the peculiar contractility characteristic of the action of striped muscular fibres. Now the paralysis of those nerves, which preside over the functions of the arterial and venous contractility, necessarily begets a stagnation of the blood in a greater or less degree. Likewise calling upon the heart to attempt to drive the current through a series of paralyzed canals, which possess of themselves no self-help, and the result is a transudation, and that transudation consequently takes place where there is found the least resistance, which is upon the mucous membrane of the walls of the stomach and the intestinal tract. We further know that atropine dries up the mucous membranes of the body, from the fauces to the rectum, whether it be in consequence of its control of the inhibitory nerves of the heart, or a tonic spasm of contraction of the muscular layers of the blood-vessels, I cannot say; but that it is a dryer of mucous membranes there is abundant evidence to show. Furthermore, we know that morphine controls spasm; that it subdues pain; that it promotes quiescence, and that it has a tendency to keep the blood-vessels, and more especially those of the spinal cord, in a distended state, thereby, for the time being, maintaining the spinal cord in a state of vascular plenitude, which stimulates to proper functioning. Without further theories upon the action of morphine and atropine administered hypodermically, I may be permitted to state that in the epidemic of 1866 and 1867 of cholera in St. Louis, and more especially in 1867, I ceased to administer medicine by the mouth and stomach, and in every case that I saw I mainly relied upon the use of the hypodermics in the stages prior to collapse, allowing the patient to have nothing but cracked ice, carbonated waters, or champagne by the stomach. The results in many of them were very satisfactory, and, unless the patients were too saturated with the cholera poison, a large majority of them did not pass into the collapse stage, particularly if dry heat were continually kept on the extremities, and friction and mustard poultices uninterruptedly and vigorously maintained. My observation as a medical student in 1854 and 1855, and my recollections as the son of a physician with a very large practice in 1849 are, that all the known methods described in 1832 and 1833 were persistently repeated, and I do not remember any two medical men who had any one special theory, or used any one form of treatment from which they derived any certain or constant benefit whatever. As a general rule during the epidemics, where medication by the mouth was persistently

tried, all patients who recovered from cholera did so not in consequence of medication, but because of the power they possessed to resist the poison, or in proportion to the intensity of the poison they had absorbed. But the epidemic of 1866 and 1867 demonstrated the rapidity with which hypodermics of morphine and atropine effectually controlled diarrhœas, in contradistinction to the uncertain and almost useless exhibition of medicine by the mouth. The deductions I have drawn from a very extended experience in the treatment of cholera is, that the disease must be attacked not in those parts where it locally manifests itself, but through the medium of a general circulation, which conveys antidotes to the prostrated and poisoned cerebro-spinal centres.

Patients dying from what is called in the South and West a "congestive chill," but which has been described in the text-books as "Pernicious Intermittent Fever," exhibit all the symptoms usually found in the collapse of cholera, the coldness of the extremities, the washerwoman's hand, the shrivelled blue skin, the aphonic voice, the sunken eyes, preceded by diarrhœa and vomiting, with this difference, that in the collapse of cholera there is a sub-normal temperature, whereas in the collapse of pernicious intermittent fevers there is always an increased temperature, going up sometimes to 106°, but the cause is evidently some poison acting in an analogous manner as does the cholera poison. There is in both diseases some form of poison which produces irritation of the cerebro-spinal centres, and prostration, and paralysis of the vaso-motor filaments of the sympathetic nerves. In the pernicious intermittent fever it is attended with congestions and engorgements of the lungs and liver, and general high temperature of the body, which is rarely, if ever, manifested in cholera. No one would attempt now to treat pernicious intermittent fever by means of the exhibition of quinine through the mouth; but there is scarcely a medical practitioner throughout the Valley of the Mississippi, where the disease is so prevalent, who does not immediately act upon the poison by means of repeated hypodermics of quinine, until the patients rally from what would otherwise be a fatal collapse. How futile to attempt medication by the mouth, to trifle with a disease like cholera, to lose valuable time when hypodermics may rapidly accomplish the results and prevent the fatal finale! What we need in the treatment of cholera is to know positively beforehand that a patient is to be subjected to an attack. During an epidemic presumptive evidence becomes almost positive testimony; and if, under these circumstances, we can manage to administer to a patient such medicaments and restoratives as will keep up the heart's action and the respiratory functions, we might so saturate him with them as to tide him over what would be otherwise a fatal attack. Such a method is generally proceeded with in cases of empoisonment for the bites of venomous reptiles, such as the rattlesnake, the copperhead, the moccasin, and the cobra de capello. Alcohol is now believed to be an antidote to snake-bites, not so much, in my judgment, because it possesses a special solvent antidotal character, but because persons bitten by reptiles can take such large quantities of it; and it sometimes requires enormous doses to stimulate the heart's action and the respiratory functions. It is this alcoholism which maintains the heart and lungs in their various functions, sufficiently long to allow the usual emunctories to get rid of the poison; or another explanation may be offered in the fact that the poison, not having time to thoroughly overpower and paralyze the cerebro-spinal centres, may be so attenuated by an alcoholic mixture in the blood that it is thrown out of the system in consequence of such alcoholic dilution. Take either definition we may, it is certain that the alcohol keeps the heart stimulated for a sufficient number of hours, in the vast majority of cases, to prevent death.

In cholera we have hitherto failed to cure by the administration of remedies by the stomach; therefore let us try the hypodermic treatment as offering the most rational methods.

Quarantine has hitherto failed to ward off an epidemic of cholera; therefore let us prevent its germination and fruition by clearing away filth and sewage, as well as promote the highest state of hygiene by teaching the community how to live during the invasion. When we accomplish these propositions we will be enabled to master the pestilence, and then only.

TRYPSIN AS A SOLVENT OF DIPHTHERITIC PSEUDO-MEMBRANE.

By HENRY DWIGHT CHAPIN, A.M., M.D.,

ATTENDING PHYSICIAN TO THE OUTDOOR DEPARTMENT, BELLEVUE HOSPITAL (CHILDREN'S CLASS).

PROBABLY the large majority of physicians who have tried solvent sprays for the destruction of diphtheritic membrane, particularly as it occurs in the larynx and trachea, have become sceptical as to their utility. A solution that is strong enough to exert a marked chemical activity in disintegrating false membrane is too irritating to be of practical utility; for all agree as to the dangers of using such applications to a diphtheritic surface. Alkalies and acids, in sufficient concentration to be very powerful, must then be ruled out. The problem to be solved in destroying pseudo-membrane is to obtain a substance that will be effectual and, at the same time, unirritating; that can be freely and continuously used without fear of aggravating the local or general diseased condition. While it is not supposed that diphtheria is cured by getting rid of the membrane, if it can only, even partially, be destroyed as quickly as it forms, we not only remove great danger from septic infection, but, in case of croup, may stave off the fearful death by strangulation until the violence of the disease begins to abate and the membrane ceases to form in the larynx. A physiological agent, by its inherent vitality, can do quickly and without harm the work that a chemical agent can accomplish only by a destruction that cannot be practically limited or controlled. In the former case, there is applied to one part of the body a ferment intended normally for another part, but still capable of being used largely under its natural conditions; in the latter instance, we are employing within the body, with its delicate, vital activities, the harsh reagents of the laboratory. The physiological, as distinguished from the chemical method, is then to be preferred in dealing with false membranes. The object of the present paper is to call attention to a ferment that promises to be of great use, from its physiological activity upon fibrous structures, in connection with diphtheritic membrane, and to urge a trial of it by the profession, with a view of determining its practical utility. It certainly seems to merit a trial. In the treatment of disease so many sources of error are possible that numerous cases must be collected before reliable conclusions can be deduced; nevertheless, single cases are often worth a careful consideration, in the line more of suggesting future possibilities than of settling any question in therapeutics. The history of the following case is hence given in full. I was called, on December 17th, to see Kate M——, aged three years and seven months. The child had been brought to my office a week previously, for a general cold, the catarrhal process extending from the nose to the bronchial tubes. This condition improved some, but on December 15th she seemed ailing again. On December 16th she complained of her throat, and had a slight hoarse cough; at the same time, the child did not appear to be very ill, and sat up to her meals with the family. When I examined her on December 17th, there was a false membrane covering both tonsils and the uvula, and extending up over the back of the soft palate, apparently into the nose. There was a thin mucous discharge from the nostrils that had excoriated the upper lip, but this discharge had existed during the previous

week. Auscultation showed the presence of a general bronchitis, by many mucous râles. There was no dyspnœa, but, at times, the child would have a hoarse, croupy cough.

On December 18th the croupy symptoms became very marked, pulse rather weak, and temperature 100°. A steam atomizer with a one to fifty solution of liquor potassæ in lime water was employed in addition to constitutional treatment. In spite of this the breathing gradually grew worse through the day. When the child was seen on the morning of December 19th, the membrane had begun to disappear from the tonsils, but the dyspnœa had markedly increased. There was epigastric and supra-sternal depression upon inspiration, and signs of deficient oxygenation. The dyspnœa continued increasing through the day, and in the afternoon it became apparent that the child would speedily die of strangulation if not relieved by a tracheotomy. This operation I performed at 5 P.M. with Dr. S. M. Roberts. The opening into the trachea was made below the isthmus of the thyroid gland, and a membranous cast of the canal was coughed out. Although the case was a most unpromising one for eventual recovery, there was instant and marked relief to the breathing following the tracheotomy. The temperature was 99½°, and pulse 140 just before the operation; immediately after, the temperature was 101¼° and pulse 155. Within three hours the temperature had risen to 103½°, and pulse to 160. The breathing continued easy through the night, although the child was rather restless. Quinine and digitalis were administered with stimulants. Early in the morning of December 20th the pulse was 165, temperature 103°, and respiration 24. The canula had been frequently cleansed during the night, and was perfectly free from mucus and false membrane; the wound was also healthy looking. As the morning advanced the breathing began to grow somewhat difficult, and by noon well-marked symptoms of tracheal croup had appeared. The canula was perfectly clean, showing plainly that the obstruction was below the tube. A feather, passed frequently down into the trachea, failed to dislodge any of the membrane, although it brought up a little mucus. The dyspnœa continued to increase, until finally, in the middle of the afternoon, the breathing was as difficult as before the operation. There was depression of the soft parts above and below the sternum, and the child tossed about in the agony of suffocation.

Feeling that I could do no more to alleviate the distressing symptoms, as repeatedly passing a feather deep down into the trachea had failed to give any relief, I left the house promising to return in an hour. Upon reaching my office it occurred to me that it would do no harm to try the digestive effects of ext. pancreatis upon the membrane that had descended out of my reach. Hurrying back to the house for fear the child might be dead before my arrival, I found her lying in the nurse's arms and apparently almost in her last gasp from the obstruction below the tube, which was still clean and free, with the canula removed to allow all possible access of air. The pulse was imperceptible. Hastily emptying one of the vials containing gr. v. ext. pancreatis and sodii bicarb. into the receiver of a hand-spray, containing about two ounces of luke-warm water, I put the nozzle at the opening of the tube and threw a strong spray directly down into the trachea. This was followed by a fit of coughing, but not by evidences of as much irritation as I had anticipated. The cough expelled several small masses of mucus, which was followed by slight relief. The spraying was frequently repeated, and in about half an hour I fancied the breathing began to get appreciably easier. Uncertain as to whether the relief was simply due to the physical action of an alkaline solution or to the physiological effects of the pancreatic ferment, I determined to continue its use. The symptoms of tracheal croup, shown by the obstructed respiration, slowly disappeared, until in several hours the breathing showed no evidence of tracheal or bronchial occlusion. During this period the pancreatic spray had been blown through the tube, about once every fifteen minutes. The disappearance of the supra-sternal and abdominal depression was gradual. There was no return of the dyspnœa through the night, or on the following day, when she died.

A point of interest, in passing, was the satisfactory action of cold compresses in reducing the temperature and restlessness. At eight in the evening, while the breathing was quite easy, she began to get extremely restless, and examination showed the temperature to be 105⅘° in the axilla, and pulse 170. I immediately had cold compresses wrapped around the chest, and repeated every fifteen minutes. Dry blankets were put outside. At ten o'clock the temperature was 101⅕, and pulse 150, with the child resting quietly. There had early been evidences of blood-poisoning in this case, shown by the pale, waxy skin and great depression, and the following morning she died from this cause. The next day I removed the larynx, trachea, heart, and lungs entire, and took them away from the house for careful examination. These specimens I afterward presented before the Pathological Society. The surface of the lungs had several small patches of emphysema, the parenchyma was congested and œdematous, and at the base of the right lower lobe there were two small patches of pneumonia. There was a dense, firmly adherent membrane attached to the whole of the inner surface of the larynx, and extending up to the tip of the epiglottis. The vocal cords were very thickly covered. There was also a thick membrane extending down on either side of the incision into the trachea to its lower border. Below the opening it stopped, and the whole length of the trachea was intensely injected, and contained little disintegrated shreds of membrane. This condition continued down into the bronchial tubes of the second order, where all evidence of the previous existence of a false membrane ceased. The presence of dense, firm membrane down to the spot in the trachea that was first reached by my spray, and its existence below this point only in shreds and partially disintegrated masses, without continuity, in addition to the marked clinical evidences in the case, satisfied my mind that the trypsin ferment in the pancreatic extract had acted in digesting the membrane. While pseudo-membrane is in a more favorable condition for maceration in the trachea and bronchial tubes than in the larynx, it could not so suddenly have disappeared by this process, as was exhibited by the clinical symptoms. The membrane in the trachea and bronchi must have been thick and abundant to have produced such prolonged and severe dyspnœa, and indeed such was its character just above and around the tracheal opening as seen after death; the most favorable conditions for maceration, with alkaline spray, could hardly have so quickly reduced it as to produce timely relief of dyspnœa, or leave so little remaining as appeared at the autopsy.

The symptoms observed before death and the appearance of the membrane afterward complete the evidence, to my mind, that a more active agent than a mere alkali had produced its disorganizing effects upon the false membrane to its almost complete destruction. To further satisfy myself, however, I tried an experiment upon the larynx, which was thickly coated with dense, firm, adherent false membrane. Putting three grains of extract of pancreas with some soda bicarbonate in about an ounce of lukewarm water, I sprayed the larynx several times, keeping the nozzle at the distance of a foot. The larynx was then put in a warm place at about the temperature of the body. In half an hour a change was appreciable in the membrane, and in several hours it was pretty completely softened and diffluent; in fact its condition was such that it could probably have been expelled during life, or at any rate not have been dense enough to have caused suffocation, although before the pancreatic spray had been used it was exceedingly tough and abundant.

It will be observed that soda bicarbonate was combined with the extract of pancreas in the above instances, as the pancreatic ferment acts better in an alkaline medium. In order to eliminate the alkaline element, I have since performed a few experiments in which the action upon membrane of the ferment trypsin, of the pancreas, was compared in efficacy with that of an alkaline solution. I had prepared a solution of trypsin (gr. iv. to ʒ j.) with one-tenth of one per cent. of salicylic acid. The reaction was slightly acid. One per cent. of liquor potassæ in lime water formed the alkaline solution. Through the courtesy of Dr. Charles Rice, I had the use of a closed water-bath, and the benefit of his assistance in regulating its temperature and in various other details in the experiments. It was my purpose, as nearly as possible, to imitate the conditions found in life, in comparing these two solutions. Accordingly, two large, long, wide-mouthed bottles were selected, and holes bored into the corks to allow the entrance of a spray. The membrane to be tested was pinned on cork and placed at the end of the bottle, that was lying in a horizontal position in the dry air of the water bath. A drachm or so of water was placed in the bottle to allow some moisture to be present. The temperature of the water-bath was kept at from about 37° to 38° C. The membrane to be tested was thus placed in a circumscribed space, at about the temperature of the body, in which there was some moisture, and could only be reached by a spray going through a hole in the cork.

I first tried the relative effects of the trypsin and alkaline spray upon a tough, fibrous membrane, having blood-corpuscles in its meshes, that was obtained from an inflamed pleura over a caseous pneumonia, part of the lung being slightly gangrenous. Two pieces of equal size and consistence were taken, pinned upon cork, and each one placed at the extremity of one of the bottles, that were lying together in the water-bath. The trypsin spray was then applied through the small opening in one bottle, and the alkaline spray through the other. In forty-five minutes, upon inspection, it was found that the membrane acted on by the trypsin spray was much softened, while that treated by the alkaline spray was apparently unchanged. The two sprays were then repeated. In half an hour more, the fibrous membrane subjected to the activity of trypsin was completely disorganized into a thin, diffluent substance, a large proportion having disappeared entirely, while that treated by the alkali was somewhat softened, but otherwise not much changed. In order to more directly test the relative effects of these substances, the trypsin and alkaline solutions were put in two test-tubes, each containing a good sized piece of fibrin derived from the same source. In fifty minutes the fibrin in the trypsin solution was completely dissolved, not a vestige remaining; that in the alkaline solution was considerably softened, but fully maintained its structure. Encouraged to find that a spray of trypsin, applied under much the same conditions as obtain during life, acted so favorably upon fibrous membrane, I next compared its effects with the alkaline spray upon diphtheritic pseudo-membrane. Two pieces of the membrane were pinned on cork, and sprayed with the two solutions as before. In an hour, after two sprayings, the membrane treated with trypsin was soft and diffluent, that treated with the alkali was slightly softened; in an hour more, after an additional spraying, the former membrane was completely diffluent, while the latter was soft, but maintained its structure. In the next trial, the diphtheritic membrane was exceedingly thick and firm, and was treated *in situ* in the trachea which was bisected, and one piece placed in each bottle. Both sprays were applied eight times during the course of two hours and a half.

In half an hour a change began to be evident in the edges and surface of the false membrane acted on by the trypsin spray, and when the two hours and a half had elapsed it was pretty completely diffluent except at its thickest part, and here, at its under side where it was in contact with the trachea, there was some trace of membranous structure remaining. At the end of the same period of time, the pseudo-membrane to which the alkali had been applied was softened, but its integrity was preserved. In the preceding experiments it was noted that the effects of the trypsin spray upon the fibrous membrane began very quickly on the exposed surfaces, a sort of soft, thin film first forming at the superficial part, and then gradually becoming more liquefied. It took longer to affect the deeper, unexposed part of the membrane, which apparently preserved its structure after the surface was completely diffluent. Finally the whole membrane would present a sort of melted appearance, destitute of organization. Foster states that the appearance of fibrin undergoing pancreatic digestion is different from that undergoing peptic digestion. In the former case the fibrin does not swell up, but remains as opaque as before, and appears to suffer corrosion rather than solution. The membranes, on the other hand, under the influence of the alkaline spray were physically a little softened, but not structurally altered at all. I next tried two experiments in which diphtheritic membrane was placed in the two solutions in test-tubes, to test their effects in this manner. In each case I was surprised to see that the trypsin solution had not such a powerful effect upon the false membrane, and that the alkaline solution disintegrated it about as quickly. It has seemed to me that the repute enjoyed by alkaline applications for the destruction of diphtheritic false membrane, is based somewhat upon the fact that experiments with the membrane have generally been in alkaline solutions. It is manifest, however, that during life the diseased surface cannot be kept in an alkaline bath, but must be reached by a spray, and it is often very problematical how much of this reaches the desired spot. The alkaline spray that I used, under the most favorable circumstances for employing this method, had very little effect upon the membrane.

The reason that the trypsin solution, as distinguished from the spray, had not a stronger effect, has seemed to me to be explained by considering that this mode of employing the ferment was not physiological. During digestion the food does not remain stationary in a limited amount of the digestive fluid, but is continually moved about, coming in contact with fresh instalments of the ferments which are continually being produced, the peptones formed being either absorbed or carried away, and do not remain to hinder the further digestion of unchanged albuminoids. Hence by spraying a membrane repeatedly with a trypsin solution, fresh particles of the ferment are deposited at short intervals upon the surface to be acted on, and in this way the physiological method is imitated. It is thus seen that the way we practically are compelled to deal with false membranes during life, that is, by repeatedly spraying, or by making local applications to the tonsils, is theoretically the best means of physiologically employing the trypsin. In order to study the effects upon muco-pus, a ropy mass was put in trypsin and alkaline solutions, it not being practical to use the spray. The muco-pus was extremely thick and tenacious, adhering to the sides of a glass and expectorated by a man suffering from phthisis in a state of softening. The action of the trypsin upon the mass was slow, but in five hours it was completely dissolved. The alkaline solution had slight effect upon the thick, slimy mass as there was little apparent change in it during the fifteen hours it was under observation. In "Foster's Physiology" it is stated that trypsin, unlike pepsin, will dissolve mucin, and that like pepsin it is inert toward nuclein, horny tissues, and the so-called amyloid matter. Professor W. Kühne, of Heidelberg, was, as far as I can learn, the first to elaborate the ferment trypsin from the pancreas. In 1876 he published two monographs on this subject: "Ueber das Verhalten verschiedener organisirter und sogungeformter Fermente," and "Ueber das Trypsin (Enzym des Pankreas)."

The ferment was found to be exceedingly valuable in histological researches, from its activity on certain tissues. R. H. Chittenden, Ph.B. ("Histochemische Untersuchungen über das Sarkolemm und einige verwandte Membranen"), and MM. L. Waldstein et Ed. Weber in a monograph ("Études Histochimiques sur les Tubes Nerveux a Myéline") reprinted from the *Archives de Physiologie*, have found its activity of service in this connection. Dr. T. Mitchell Prudden tells me he has used trypsin satisfactorily in histological studies, and that by means of it he has been able to separate the cell territories in cartilage, dissolving the basement substance.

It naturally follows that the discovery of a ferment having such activity upon normal tissues, would further suggest the possibility of utilizing it in the destruction of pathological products. I find in the *Edinburgh Medical Journal* for March, 1884, the abstract of an article from the *Berliner Klinische Wochenschrift*, by Dr. Schaeffer, in which papayotine is recommended in the treatment of diphtheritic membrane. Papaine, or papaw, is an extract from the acrid, milky juice of *Carica papaya*, the papaw tree. Professor Dr. C. A. Ewald, editor of the *Berliner Wochenschrift*, supplements this paper as follows: Seeing that the influence of papayotine upon diphtheritic membranes has now been confirmed from many sides, seeing that its action is local, and having regard to its costliness, Ewald suggests the employment of a powerful pancreatine. The action of papayotine is manifestly not a specific one especially directed against diphtheritic membranes, but is founded on this, that it represents in alkaline or neutral solution a very powerful ferment which can dissolve coagulated albumen. Pepsin has failed because it is only effective in acid solution, and the mouth fluids are usually alkaline or neutral. But pancreatine, either dry or contained in a glycerine extract of the pancreatic gland, offers us a similar preparation to papayotine so far as regards its albuminolytic properties, and whose cost is much less. The selection of therapeutic materials with which to combat such a malignant and deceitful disease as diphtheria cannot be too large. But let no man believe, either in papayotine or in any other means directed against the local process, that he has found a prophylactic against systemic infection. Dr. B. M. Van Syckel, of this city, tells me that while studying with Kühne at Heidelberg, the use of trypsin upon diphtheritic membrane suggested itself to him, but it was not until last November that he tried it in a case of false membrane upon the tonsils with a favorable result. He has been able to digest diphtheritic membranes in a trypsin solution (one in ten) at the end of fifteen minutes. The membrane was then entirely dissolved with the exception of a small residue, which somewhat resembled the powder-like precipitate often seen in urine. This residue, under the microscope, showed epithelial cells, some fibrous tissue, and bacteria.

Dr. Van Syckel has lately received from Professor Kühne the following method of preparing pancreas for a trypsin solution: "Take fresh or one day old pancreas from the ox; hash it fine and add four to five volumes of absolute alcohol; let stand five to six days, then drain off alcohol, and add fresh absolute alcohol, two volumes; let this stand three days; drain again and extract the substance with ether; the pancreas can then be quickly dried in air. To five grammes of pancreas, so prepared, add 50 c.c. of 0.1 per cent. salicylic acid solution; let digest in a water-bath four hours at temperature 37° to 38° C.; filter, and to filtrate add sodæ bicarb., to make slightly alkaline, say about 0.25 per cent. The fluid is then ready for use. It is best to add one per cent. thymol to the solution to prevent putrefaction. This addition of thymol in no way interferes with the action of the fluid." Dr. Van Syckel has prepared a trypsin solution by adding five grammes of the prepared extractum pancreatis to 50 c.c. of the salicylic acid solution, etc., as above. He states that a trypsin solution, prepared correctly, should dissolve its weight of fresh blood-fibrin in ten minutes, and that all preparations requiring a longer time are poor. The trypsin solutions I used were made for me by Mr. Fairchild and represented by assay the strength of about gr. iv. to ʒj. To avoid decomposition, various antiseptics were added; to some of the solutions one-tenth of one per cent. of salicylic acid with a little thymol, and to others a three per cent. solution of boric acid and borax, combined to form a neutral medium. We are now experimenting on this subject, and hope soon to determine the best antiseptic to use, that will preserve the ferment without inhibiting its action, and possibly be valuable in disinfecting the diphtheritic surface as well. Of course, any antiseptic must be used in extremely small quantities to avoid interfering with the activity of the ferment. I have tried the trypsin solution in a number of cases of diphtheria, in which the membrane was abundant upon the tonsils and fauces, with favorable results. It should be applied at short intervals by the spray or brush; in the few cases in which I have thus tried it, the membrane has disappeared more quickly than is usual in my experience. As the ferment is locally unirritating, it can be very frequently applied as long as the membrane continues to form. A few drops of the solution placed in a dog's eye showed no signs of irritating. Upon living tissues, the power of the ferment does not seem to be very great. All the physical conditions in the fauces, pharynx, and larynx are favorable to its action.

The important question, as to whether a trypsin solution can practically be utilized to dissolve false membrane within the larynx and upon the vocal cords, remains to be solved. If the membrane can be disintegrated as quickly as it forms, the necessity of tracheotomy may sometimes be avoided. To this end it is of paramount importance to thoroughly apply the ferment within the larynx. It has always been a matter of uncertainty to me how much of the spray, as usually applied to young children, actually reaches the glottis. In cases in which the steam atomizer is used, it is rarely possible to get the child near enough to inhale the spray, which is usually fine, in very great concentration. When the nozzle of the hand-spray is placed in the mouth, they at once gag, the back of the tongue rises, and prevents the entrance of the medicated spray; for when the tip of the nozzle is touched, the spray stops at once. To avoid this trouble I have had made by Tiemann an instrument with a rounded nozzle that can be thrust into the mouth of a struggling child without fear of doing any harm, and a projecting depressor that reaches forward very nearly to the tip; this at the same time holds down the back of the tongue and prevents the stopping of the spray from the contact of the soft parts. By means of a double bulb, or possibly at times by compressed air, a continuous downward spray is maintained.

It is thus aimed to fill the pharynx and larynx with a trypsin spray of sufficient tension to penetrate all parts. I have only been able thus far to try the trypsin in one case of diphtheritic croup, and that with negative results, as the baby, nine months old, was moribund when I saw her. If in any instance, after tracheotomy, we are able to keep the air-passages below the tube tolerably free from membrane, by this agent, it will be a great gain.

The extract of pancreas, while exerting a digestive effect upon diphtheritic membrane, does not act quite so quickly as trypsin, in the cases in which I have compared the action of the two, upon fibrous membrane. In the case cited at the beginning of this paper, however, the extract certainly had a timely and favorable action. Professor J. Lewis Smith has used the extract of pancreas upon quite a number of cases of diphtheria, and considers its action promising. With reference to the manner of applying it I have had Mr. Fairchild make me up quite a number of solutions, and as a tentative formula, it has seemed to me the following is as good as any:

℞. Ext. pancreatis..... gr. xv.
Sodii bicarb..... gr. iij.
Glycerinæ..... ℥ j.
Aq. dest..... ℥ vij.

It can be used by spray or brush. Stronger solutions do not appear to act any quicker, while being more viscid. Enough soda is added to make the solution alkaline, and the glycerine to enable it to catch hold of the membrane readily. As stated at the beginning of this paper, before any definite conclusions in therapeutics can be reached, many observations by different observers are necessary. It certainly seems as if efforts to reduce the mortality of diphtheria are continually needed. A disease that kills more than cholera cannot have trials made in too many directions to partially control it.

CONCERNING THE NEW TREATMENT FOR GONORRHŒA.

By E. BLACKWELL, M.D.,
NEW YORK.

Some few months ago there appeared in one of our medical journals an article on the "Treatment of Gonorrhœa," and as the treatment partly consisted in the use of a very reliable antiseptic and germicide, namely, bichloride of mercury, it struck many at once as being a sensible remedy, even if not a practical one, which, of course, could only be ascertained by experience.

Those who were naturally most taken with the idea were the specialists in this line, and I was led to make trial of the same through the influence of one of these specialists.

The process consists first in running through the urethra, from a fountain syringe, two or three quarts of warm water. The catheter is passed back beyond the inflammation in the urethra, and then the water is turned on and allowed to run through the catheter, and so on out again by the side of the catheter, not entering the bladder. The water first is made comfortably warm, and gradually made warmer until the patient complains of it being too warm; thus of a gradually warmer degree about three quarts are allowed to run through. Then immediately after a solution of $\frac{1}{1,000}$ to $\frac{1}{2,000}$ of the bichloride is passed through in the same manner. After three or four such injections the germs are supposed to be killed, and the patient promptly recovers.

My experience thus far is comparatively limited, only having tested it on four cases, in two of which the treatment was successful and in two not.

The first case that presented itself to me, and upon whom it worked successfully, was one whose discharge appeared about thirty-six hours after intercourse. This short period of incubation led me to think it was urethritis, and I still think it was. After the first injection the discharge was at no time more than a moistening of the lips of the urethra, and after the fourth injection I dismissed him well.

The second case was where the discharge came on about four days after exposure, and which had been discharging for twenty-four hours before I saw it. This treatment was commenced at once, and was kept up until five injections had been given him in five consecutive days, after which the discharge began again, and I put him on the old-established treatment. During the time of giving the injections the discharge was very little.

The third case was one again where the discharge came on about forty-eight hours after exposure, and he came to me immediately. After using three injections, as described above, the discharge ceased and did not return.

The fourth case was one where no discharge appeared until the eighth day after exposure. Being anxious to make a more extensive and thorough trial of the treatment, I gave this man nine injections, as I was positive it was gonorrhœa. After he had taken the nine injections, ranging from a $\frac{1}{3,000}$ solution to a $\frac{1}{2,000}$ solution, he came back on the second day following the last injection with a discharge as bad as in the beginning, and I was compelled again to resort to another kind of treatment.

In the above cases there was every indication that the two instances where the new remedy worked well were simply cases of urethritis, and the two cases where it failed were without doubt, in my mind, true gonorrhœa. Hence from this small data I came to the conclusion it had no merits in the treatment of true gonorrhœa, or at least would not effect a cure within the limits prescribed for it.

355 Lexington Avenue.

ABSCESS OF THE LIVER, WITH ECHINOCOCCI—RECOVERY.

By NATHAN MAYER, M.D.,
HARTFORD, CONN.

On September 29th I attended Mrs. F——, a woman of about thirty-eight years of age, small and slender, married but childless. She exhibited the symptoms of a bilious fever, deeply icterous skin, bilious vomiting, pain in the epigastrium and right hypochondriac region, and exacerbations occurring every other night. The fever, commencing with a chill, brought, in the succeeding stage, the thermometer up to 103½°. She experienced two more exacerbations after I began treatment, until the quinine, gradually increased to a thirty-grain dose, prevented their recurrence. The same remedy was for some days continued in smaller quantities with mercurials, and then dilute nitro-muriatic acid substituted. The symptoms subsided and the woman made, to all appearance, a fair recovery. My final visit at this time took place on October 25th, nearly four weeks after the first call.

I was again summoned on November 9th. She was in bed, complaining of great pain in the right hypochondriac region and of dyspnœa. Local applications of dilute aqua regia were ordered, and small doses of morphine. This seemed to relieve her in a measure, but some dull pain over the liver remained. The yellow color of the skin, which had been largely dissipated, was again deepened, occasional bilious and mucous vomiting occurred, and a moderate degree of fever became continuous, with a small pulse of about 106. The alvine discharges, which were not irregular, exhibited at times a normal, and again a light yellow color.

In the course of a month the liver had increased in size so that its margin could be felt in a line an inch below the umbilicus, which, coming from the right, swept around the navel and nearly two inches to the left before it ascended to the epigastric region. It bulged out moderately in three separate portions, the highest being a little above the umbilicus, and this latter developed fluctuation.

On December 4th, with the assistance of Dr. Morrissey, a Flint trocar of moderate size, having aspirating apparatus attached, was introduced one inch to the right and two inches above the umbilicus, and carried to its full length. About a third of a pint of pus being withdrawn, the flow ceased; detaching the aspirator the canula was cleared, and as much more of extremely fetid pus escaped. The tube was left in place, and covered with the segment of a rubber ball; this filled many

times, and on the two succeeding days pressure always caused a profuse escape. On the third day a large flexible catheter was introduced, and the cavity washed out with carbolic solution ; this brought to light several small cysts.

Next day, and for the first time since the operation, a very large passage of the bowels was effected, the demand coming with great suddenness. The fecal mass contained over a hundred echinococci cysts of all sizes, large ones, with smaller studding their walls, or small and very small ones afloat independently. The microscope showed abundance of the characteristic hooks, but I did not succeed in seeing a complete scolex. Two days after this, a fit of vomiting discharged a very large quantity of ruptured cysts, their size much surpassing those first evacuated, and from this time small cysts continued to come by the opening in the abdomen and larger ones by stool. Those that came from the opening, which discharged great quantities of bile, were much tinctured by the latter, and occasionally shreds of capsule, tough, fibrous, and of all shades of yellow, accompanied them. The alvine discharges became clay-colored, and then like plaster ; only an occasional portion showed normal tints. With them were cysts and white shreds of capsule.

The patient was not uncomfortable during this time. Some febrile reaction in the first days, attended by a small pulse of 120, was followed by a season of debility, with extremely irritable stomach, but without great pain or discomfort. Some time early in January the last cysts came, and about the middle of the month the opening into the liver made efforts to close. At first these caused sharp pain and some dyspnœa, but soon the temporary occlusions were better borne, and when at last the fistula healed, no serious inconvenience resulted. The fæces that had retained their clayey character assumed a yellowish tint, and they present, since the closure, an altogether more normal appearance. During the last weeks a continuous stream of bile had passed from the fistula.

The patient is at present up and doing well, with the liver reduced to little more than its normal size, and no tenderness of the part on pressure. She eats and digests well, and presents appearances of anæmia only, which are yielding to treatment. There seems every indication of a recovery.

I presume that the abscess of the liver, caused by the pressure of the echinococci mass, was formed outside of its capsule, since only fetid pus was the result of its puncture. Later and repeated agitation of the canula, inserted for a length of three inches, may have penetrated the encapsuled cyst and admitted bile. This, authors claim, causes the destruction of the vitality of the cysts. The puncture was too small for any but very diminutive cysts to escape, and, on the third day, an opening into the duodenum was probably effected, and the mass of cysts passed out that way. The size of many precludes the idea of an escape by the ductus, inasmuch as some that came out unbroken were an inch and a half in diameter. That the opening was into the duodenum appears likely by the extensive vomiting of large ruptured cysts, which took place six days after the operation. What the bilious fever, in the first place, had to do with the affair, I am at a loss to imagine, unless it marked the location, or first disturbance by growth of the echinococci eggs and the resulting inflammatory reaction of the liver. But authors accord a long time to the development of these cysts, while the patient had, by all accounts, not suffered previously. An endeavor to trace the acquisition of the trouble resulted negatively. There is a dog in the family, and a great pet. They live in poor circumstances, and crowded together in three small rooms. It is by no means impossible that a tapeworm link, passing the dog, should have come in contact with provisions prepared for the people. But I have been unable to establish the presence of tapeworm in this dog, though the fæces were repeatedly inspected. Still it is possible he may be so afflicted.

A CASE OF PRIMARY EPITHELIOMA OF THE TONSIL.

By F. DONALDSON, Jr., B.A., M.D.,

CHIEF OF CLINIC FOR THROAT AND CHEST, UNIVERSITY OF MARYLAND.

Malignant disease of the tonsil, and more particularly epithelioma of that gland is, according to all observers, so rare that any authenticated case of such disease may well bear reporting.

Poland says, "Cancer seldom attacks the tonsils, and this is remarkable considering the amount of friction from, and contact with, all kinds of substances, and the intimate connection of this gland with the lymphatic system." Doubtless the apparent immunity of the tonsils from cancer, occurring as a primary or even as a secondary growth, may be in a measure accounted for by the confusion which formerly prevailed in the nomenclature of such tumors, together with the want of characteristic signs in the earlier stages of malignant tonsillar disease. And so many such cases have been diagnosed as simple hypertrophy. In old literature the terms "scirrhus," "encephaloid," "medullary," etc., were applied indiscriminately. Jourdain,[1] for instance, described all simple hypertrophies of the tonsil as cancerous ; while Bell, on the other hand, declared that the tonsil was never attacked by cancer.

Malignant disease of the tonsil is most often met with as a secondary growth, extending from the tongue and soft palate, though it is curious how often the tonsil itself escapes. Dr. Whistler[2] gives an interesting case of this kind, reported by M. Weiss in the *Revue Medicale* for December, 1881, where a malignant tumor, having all the appearance of a cancerous tonsil, proved at the autopsy to be a sarcoma of the pharyngeal wall, the tonsil itself being atrophied and pushed downward to the side of the tongue.

My immediate purpose is not, however, to give the history of the cancer of the tonsil, but to relate the following case of primary epithelioma of this gland, which occurred in my clinic at the University of Maryland :

M—— F——, an Irish laborer, aged sixty-four, came to my clinic for diseases of the chest in the latter part of last March, complaining of a "lump" in his throat. He stated, in reply to my questions, that he had never been sick in his life ; that he was, and had always been, a sober man ; that he had neither hereditary nor constitutional taint, and, finally, that his throat had given him annoyance until some six weeks before, when he became conscious of a "lump" in his throat, which had become gradually more troublesome, impeding deglutition and enunciation, until he had been driven to seek some relief for his uncomfortable symptoms.

The subjective symptoms and physical signs, as found in this patient, I would especially emphasize, for with the exception of the age of the patient there was no ground for a diagnosis of malignant disease, and the symptoms presented no departure from those of inflammatory tonsillar affection.

The patient was strong and well nourished, had lost no flesh, and had had no pain in the region of his neck or ears, nor in deglutition. He had had no fever withal, and there was no glandular enlargement. His voice had the peculiar nasal tone of enlarged tonsils, and deglutition was slightly impeded.

On examination, the left tonsil was found considerably enlarged, very vascular, and soft ; its surface smooth and unbroken except by the fissure mentioned below, and of a grayish color, the follicles secreting a thick cheesy matter. There was no ulceration. The tonsil was free and not attached at any point to the faucial pillars. It extended downward somewhat below the normal situation of the tonsil ; the lower end was quite large and projected outward, lessening the lumen of the pharynx, so as to

[1] Traité des Maladies de la Bouche. Paris, 1778.
[2] Medical Times and Gazette (London), May 26, 1883.

slightly impede swallowing. There was a fissure about the centre of the growth, extending antero-posteriorly, and nearly dividing it into two parts. There was no infiltration of the tongue or soft palate. Finally, the diagnosis of simple hypertrophy was made, and with little trouble the growth removed with the cold snare, and the patient dismissed with instructions to return if it troubled him further. He was not seen again until June 10th, when he came to have the tumor removed. I found it as large as in the first instance, and of a darker color. There was no glandular swelling, and no ulceration, either of the tumor itself or the faucial pillars. I removed the growth with the galvano-cautery, and suspecting that it was malignant, asked the man to come and see me shortly. I saw him once or twice six weeks later and removed a piece of the tumor as before. About the middle of September, however, he came complaining of pain in mastication and of difficulty in swallowing. He had flashes of acute pain, chiefly at night, in the left ear, the glands of the neck were somewhat enlarged, and a distinct hard swelling could be felt just back of the angle of the jaw. Examination showed that the tumor, though no larger, was considerably harder than before; it was of a darker color and ulceration of the surface had begun.

The follicles secreted a thin watery matter. From the above general symptoms and physical signs I was convinced that the growth was malignant; that I might ascertain its exact nature, however, I removed a large piece from the centre of the tumor and sent it to Professor Councilman, of the Johns Hopkins University, who kindly sent me this report of its pathological character:

"The specimen submitted to me for examination has all the histological characters of a true carcinoma. On section I find islands of epithelial cells, and between these a connective tissue rich in embryonic cells."

The malignant character of the growth having been settled beyond question, and it having been removed several times by the galvano-cautery and cold snare only to grow again, I thought it but right that the patient should have the advantage of a radical operation. Professor Tiffany was consulted as to the advisability of such an operation, and after examination gave it as his positive opinion that surgical procedure was not justifiable. The patient is now under constant observation and is, I regret to say, growing slowly but surely worse. The pain, particularly that referred to in the ear, is more constant and acute; his ability to take solid food greatly impaired, the tumor itself and the glands of his neck quite painful on pressure. The side of the tongue is now involved, and there is considerable ulceration and induration of the anterior pillar of the fauces. It is now nine months since the tumor began to develop, and there are as yet no very extreme symptoms, such as expulsion of the food through the nostrils, or vomiting of the same. There has been no hemorrhage of importance. The duration of life in this case, therefore, promises to be longer than the average in cancer of the tonsil. The removal of the tumor in former months has undoubtedly added to his comfort and prolonged his life.

After a careful survey of the available literature of the subject, I find that out of a total of seventy-one cases of primary cancer of the tonsil on record but nine were true epithelioma.

Pierm[1] claims to have a record of five such cases, but of these, two are so very doubtful that we are quite justified in throwing them out. With this exception, then, the nine cases are reported as follows:

Erichsen,[2] Cheever,[3] Lennox Brown,[4] Delavan,[5] Whistler,[6] and the writer, each one case; Pierm,[7] three; total, nine. Epithelioma of the tonsil, then, if we may judge from the above cases, would seem to be the rarest of all forms of cancer of the tonsil; but obviously we have no right to draw such a conclusion, for although some of the seventy-one cases recorded under the general term cancer may have been, and probably were, true epithelioma, still their accurate description is wanting, and it is therefore impossible to get at even their comparative frequency. Pierm and Cozzolino[1] state that epithelioma of the tonsil is as frequent as scirrhus and somewhat less frequent than sarcoma.

Liability to cancer of the tonsil is limited to no particular age or sex. The youngest case on record is that of a woman aged twenty-one; the oldest that of a man aged sixty-four.

Epithelioma attacks either tonsil indifferently, though there is no case on record in which both tonsils were affected simultaneously. Of the nine cases of epithelioma given, seven were examined microscopically, and the result of these examinations would seem to show that there are two pathological varieties of epithelial cancer of the tonsil; one composed of cylindrical epithelium, developed at the expense of the mucous glands themselves, and the other made up of nests of epithelial cells, developed from the epithelial covering of the tonsil itself.

Epithelioma of the tonsil presents, at its beginning, a group of general symptoms and local signs, common with other varieties of cancer, and with simple hypertrophy of that gland. An occasional hardness of the tonsil, and perhaps a longitudinal fissure of its substance, seem to be the only local signs of the disease in its incipiency. Its growth is very slow, and in but very few cases is the patient aware of his trouble from the first. Some slight pain and difficulty in deglutition, from the size of the growth, are the first symptoms of the malady. In my own case, the difficulty of deglutition complained of when first seen was caused by the size of the tumor, as there was at that time no infiltration of the surrounding muscles. At present, however, this dysphagia is from the latter cause.

In advanced cases of tonsil cancer, return of the food through the nose and constant vomiting are not uncommon symptoms. A prominent and distressing symptom in my patient at present is the intense reflex pain in the ear, which is to be found in all cases of malignant disease of the tonsil. In Delavan's case, the pain in the ear occurred long before any disease of the tonsil itself was discovered, and he relates a case in which otalgia, due to reflex irritation from malignant disease of the pharynx, was treated for some time before attention was directed to the throat. In many cases the hearing is gradually impaired from pressure of the growth upon the Eustachian tube. Pressure upon the tonsil itself, and upon the infiltrated glands, gives rise to considerable pain in the above case.

Cozzolino[2] thinks that the color of the tumor in malignant disease is to a certain extent diagnostic, it being a dark grayish-red in epithelioma, and bluish in scirrhus and encephaloid. The globular form of the tonsil is less altered in scirrhus and sarcoma than in encephaloid and epithelioma, where (in the latter especially) it frequently presents ramifications. A generally described characteristic of the last form of cancer of the tonsil is a fissure or sulcus which runs antero-posteriorly across the diseased gland. It was present from the first in my own case. Finally, the tumor is much harder in scirrhus than in the other varieties; though epithelial cancer attains a much greater growth than the other forms mentioned above.

Another marked symptom of all malignant diseases of the tonsil is the glandular enlargement, which is a most important factor in determining our diagnosis.

This enlargement is generally on the same side as the diseased tonsil, though Pierm says that he has seen the glands of the opposite side affected. It is most always found when the tumor begins to ulcerate, and in my case the ulceration of the tonsil preceded the glandular en-

[1] Sui tumori maligni delle tonsille. Morgagni, Napoli, 1884. No. 26
[2] Loc. cit.

largement. The infiltration of the glands of the neck would seem to be slower and less pronounced in scirrhus and sarcoma than in the epithelioma and encephaloid, and so we generally find greater glandular degeneration and ulceration in the latter than in the former.

The course of epithelioma of the tonsil is slow; the soft palate, the tongue, and the pharynx are successively invaded, the growth extending upward and downward until it ends the sufferer's life. The duration of life in this disease is short, generally not more than nine months. Death is slow and painful as a rule, though in two of the cases mentioned above it was very sudden.

A positive diagnosis of cancer of the tonsil can be given only after microscopic examination of the diseased gland, which should be done at once, "for if a diagnosis could be made before the disease had attacked other parts, the gland might be extirpated with more or less ease, and by natural passages, thus avoiding the formidable operation by external incision, and decreasing the probability of recurrence."

The prognosis in all such cases is very grave, and the treatment at best but palliative, unless the growth can be removed in its very incipiency. A radical operation later seems hardly justifiable. Froelich,[1] however, mentions a case successfully operated upon by Professor Czerny; Quintin,[2] one which showed no sign of return after one year and a half; and Mikulicz,[3] the case of a woman operated upon by himself, which had not returned six months after.

Below will be found (what I think to be) a complete list to date of all cases of cancer of the tonsil to be found in medical literature.

Morell Mackenzie,[4] 7; O. Weber,[6] 7; Lennox Browne,[6] 6; Sibley,[7] 6; Velpeau,[8] 5; Lebert,[9] 3; Whistler,[10] 3; Bryant,[11] 2; Cheever,[12] 2; Erichsen,[13] 2; Langenbeck,[14] 2; Baker,[16] 2; Pierm,[16] 5; Albert;[17] Burnett;[18] Quintin[19] (successfully removed); Coppy;[20] Cluttow;[21] Delavan;[22] Cozzolino;[23] Desormeaux;[24] Houël;[25] Froelich[26] (successfully operated on); Foulis;[27] Lawrence;[28] Lobstein;[29] Mason Warren;[30] Meissner;[31] Mikulicz;[32] Roux;[33] Vogel,[34] and the author, each one case. Total, 71.

A Test for Sugar in the Urine.—Dr. J. F. Kemper, of Keokuk, Ia., writes: "Dr. J. North, Professor of Chemistry in the College of Physicians and Surgeons, Keokuk, Ia., has for several years given his classes in the chemical laboratory the following test: Place one or two drops of the suspected urine on a piece of bright tin, heat over a lamp until evaporated, and then continue the heat a few moments; if sugar be present, it will be accurately indicated by the characteristic odor of burnt molasses, and by the puffy, carbonized appearance; if no sugar be present, it will be as distinctly shown by the characteristic odor of urine and by a bright, smooth, varnish appearance on the tin."

Clinical Department.

OLEATE OF COCAINE.

Dr. Chas. J. Lundy, of Detroit, Mich., calls attention to the oleate of cocaine as a superior preparation to the muriate. He has conducted numerous experiments with this salt, and has tested its therapeutical value in a number of eye diseases. One advantage is that of economy, as a much smaller quantity may be used, probably because it is not diluted and washed away by the tears. The anæsthetic effect with a five per cent. solution was found to be much greater than with a like quantity of the muriate. Within two minutes after the placing of one drop in the eye, the sensibility of the cornea and conjunctiva was almost entirely abolished, and in three minutes there was absolutely no sensation. With a single drop the period of complete anæsthesia was short—not over seven minutes—and in fifteen minutes sensation was nearly or quite normal. In eight minutes after the instillation of one drop, the pupil was perceptibly enlarged, and in twelve minutes it was widely dilated. In ten minutes there was slight failure of accommodation, but it was at no time very marked. The effects upon the pupil lasted several hours. In experiments in which one drop was placed on the conjunctiva every three minutes for four or five times, a considerable influence was exerted over the ciliary muscle; there was much greater failure of accommodation than the author had ever observed from a very free use of the muriate. The contractile power of the ciliary muscle was completely restored in two or three hours, but the pupil did not return to its normal size, after the instillation of several drops at short intervals, until the expiration of twelve or fifteen hours. The oleate has given great satisfaction also when employed therapeutically. In granular lids with photophobia and blepharospasm, in phlyctenular keratitis, etc., cocaine, and especially the oleate, is a most valuable drug. The oleate is much preferable when there is considerable lachrymation, as an aqueous solution is liable to be washed away before it performs the work required.

IS HERPES ZOSTER CONTAGIOUS?

Dr. Isaac V. Mullen, of Alexander, writes: "Having seen in the last Record the report of the case of herpes zoster by Dr. Klamann, affording suspicion of its contagious character, I will add another that happened recently in my practice. A young lady came home, a distance of fifty miles, on account of having herpes zoster. It occupied the space from the sternum to the centre of the back. Three weeks from the time she came home, her mother, an old lady, was attacked with the same disease, commencing on the side of the nose, passing over the side of the forehead, and terminating near the neck. Both cases were protracted and severe."

FAILURES WITH COCAINE.

Cocaine would be a more marvellous drug than even its most enthusiastic advocates claim it to be, did it not fail occasionally. Nothing is certain but death and taxes, and for most physicians we may even omit taxes from this short list. It is, therefore, not surprising that the use of cocaine, as well as that of every other remedial agent, should sometimes fail to respond to the confident expectations of the practitioner. It is, however, greatly to be desired that physicians should chronicle their want of success in individual cases, since by a study and a grouping of such cases it may be possible to limit with accuracy the applicability of this most useful drug, and also to discover, and consequently to avoid in the future, the causes which lead to this disappointment.

Dr. T. M. McIntosh, of Thomasville, Ga., reports the case of a person sixty years of age, suffering from chronic irido-choroiditis, complete circular synechia, and glaucomatous tension of the second degree. During the past eighteen months the pain in the eye and parts supplied by the fifth nerve had been at times very severe. Before attempting iridectomy, twenty-five drops of a four per cent. solution of Squibb's cocaine were instilled into the eye during a period of thirty minutes. The speculum and forceps caused considerable pain, as did also the incision. When the iris was grasped the pain was so intense that the patient cried out in agony, and the operation was temporarily suspended. Several more drops of the solution were instilled into the eye during the following ten minutes. The iris was now grasped, but the same degree of pain was experienced, and the operation was completed with much suffering to the patient. That the fault did not lie with the solution used was proven by its successful employment in other cases. The writer refers to the case reported by Dr. Spalding in THE MEDICAL RECORD of January 17th, which was very similar to his. He believes that the cause of failure in both instances was that the eye tension prevents absorption. In some cases of iritis the pupil will not respond to the strongest solutions of atropine, until the tension is relieved by paracentesis of the cornea, when, absorption being permitted, dilatation at once occurs.

Dr. F. Carrow, of Bay City, Mich., has had his faith in the value of cocaine somewhat shaken by a want of success in two instances. The first case was that of a boy eleven years of age, who was brought for the purpose of having an anterior hypertrophy removed from the middle turbinated bone. It was decided to transfix the growth and remove it with a Jarvis snare, and as a preliminary, a pledget of cotton soaked in a five per cent. solution of Merck's cocaine was applied over the growth and adjacent mucous membrane. This was allowed to remain in position some fifteen minutes, and when it was removed an attempt was made to transfix the parts. But, although the needle was passed very superficially, the pain was not lessened in the slightest degree despite repeated applications of the cocaine. The second case was one of stricture of the lachrymal duct, and before attempting to pass it, it was determined to slit up the lower canaliculus. A four per cent. solution of McKesson & Robbins' was applied directly over the lower puncture and the tract along which the knife was to pass. At the end of twenty minutes the patient complained of excessive dryness of the tongue and dizziness, and the pupil was widely dilated. The operation was then performed with a probe-pointed Weber's knife, and produced the usual amount of pain. Before passing the probe two minims of the solution were placed in the sac, but the pain of the operation caused bitter complaint on the part of the patient, and great disappointment to the operator.

IMPOTENCE AND HERNIA.

DR. E. A. BEAN, of St. Albans, Me., sends a report of the following peculiar case: "A man, now about sixty-five years of age, a farmer, held a captain's commission in the late war. While on duty he accidentally stepped into a hole, throwing up his arm in the attempt to preserve his balance, and soon afterward discovered that the effort had caused a hernia in the right inguinal region. Since that time he has never had a desire to approach a woman, and his penis has shrunken until it is now no larger than that of a small child. Previous to this accident he was in good health and possessed his share of the animal nature, but since that time he has never had an erection. He never had syphilis or any other venereal affection, and is sober and reliable. The testicles are apparently normal." Dr. Bean has been unable to find any record of a similar case, and would like to know the cause of his patient's loss of virile power and sexual appetite.

Progress of Medical Science.

A NEW THEORY OF THE MENSTRUAL PROCESS.—The following are the salient points in the interesting work of Dr. Loewenthal, which was recently published in Leipzig (*Allgemeine Med. Central Zeitung*, January 3, 1885): 1. The periodical flow of blood from the genital organs of the female is not the consequence of the (for the most part coincident) rupture of a Graafian follicle, but the result of the shedding of the mucous membrane lining the uterus, which is independent of the rupture of the vesicle, and takes place before it. 2. The formation of the menstrual decidua is due to the embedding of the very last ovum set free in an unfructified condition from the ovary. 3. It at once transforms itself into the decidua of pregnancy, if the embedded ovum becomes fructified, and it is shed in consequence of the death of the ovum, if this remains unimpregnated. 4. During menstruation the bursting of the vesicle and the menstrual bleeding have no other causal relation to one another than is to be found in the causes and conditions simultaneously present affording a favorable opportunity for the bursting of a matured follicle. 5. The coincidence of the bursting of the vesicle and the flow of blood is consequently no necessary one, and either can appear independently of the other. A vesicle can burst without there being present at the time a menstrual decidua. The secondary consequence of the escaped ovum, *i.e.* the menstrul bleeding, can appear without a new vesicle bursting at the same time. 6. The periodicity of the menstrual flow is dependent upon the vitality which the ovum is capable of maintaining outside of the vesicle when embedded and remaining unfructified. The general or individual variations in periodicity depend upon the shortening of, or entire want of this extra-vesicular life, whether it be idiopathic or caused by intervening influences. 7. For impregnation to take place an ovum usually freed from the vesicle at the time of the last menstruation must be always present, normally in the uterus, in abnormal cases somewhere outside of it.

THE ELIMINATION OF LEAD BY THE SKIN.—Professor Du Moulin has recently communicated to the Academy of Medicine of Brussels the results of his experiments and observations on the excretion of lead by the skin. The conclusions drawn from his paper (*Revue Médicale*, November 29, 1884) are: 1. That the skin of all persons suffering from saturnine affections that he has examined (fourteen in all) contains lead in sufficient quantity to give a reaction when a glass rod wet with a five per cent. solution of mono-sulphuret of sodium is brought in contact with it. 2. In recent cases the reaction is much more pronounced than in those of long standing. 3. Washing with either cold or hot water removes only a few epidermic scabs containing lead. The filtered fluid does not contain lead in a soluble form. 4. Prolonged washing with the tartrate of ammonia removes from the skin the property of blackening with the sulphuret of sodium. 5. The water used in this washing contains all the lead which had existed as an insoluble salt, but had been rendered soluble by the ammonium tartrate. 6. The sulphuret of ammonium and the mono-sulphuret of sodium precipitate a considerable quantity of lead as a sulphuret. 7. The surface washed with the tartrate of ammonia no longer reacts with the sulphuret of sodium; the deposit formed upon and within the epidermis is completely removed. 8. The surfaces of the body which do not react with the sulphuret of sodium after prolonged washing with the tartrate of ammonia after a few days are found to do so. 9. The reaction, which is only barely apparent after one or two days, increases from day to day. 10. The lead is carried to the skin and becomes lodged in it by means of the cutaneous secretion, but up to the present time we are ignorant how this body, naturally insoluble, is brought to the skin or fixed in it. New researches may throw light upon this point.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 7, 1885.

THE DUTIES AND RESPONSIBILITIES OF APOTHECARIES.

THE Apothecaries' guild is an old one, although the name does not date back much farther than the time of Henry VIII. It is, however, derived from the Greek Απο Θηκη, and was used by Galen in the first century for the place where he kept his medicines. Shakespeare, in the play of "Romeo and Juliet," gives an interesting description of this important member of society as he appeared in the great dramatist's day. He says :

> "I do remember an apothecary,
> And hereabouts he dwells, which late I noticed
> In tatter'd weeds, with overwhelming brows,
> Culling of simples ; meagre were his looks
> Sharp misery had worn him to the bones,
> And in his needy shop a tortoise hung,
> An alligator stuffed, and other skins
> Of ill-shaped fishes, and about his shelves
> A beggarly account of empty boxes,
> Green earthen pots, bladders and musty seeds,
> Remnants of pack thread and old cakes of roses
> Were thinly scattered to make up a show."

Other writers have described apothecaries in prose and verse, but no one in recent times, after visiting one of the luxuriously appointed drug stores of our large cities, would think of plagiarizing Shakespeare's language.

The title of apothecary is a broader one than druggist, although in general usage it has now become synonymous with it, and unless there is special legislation on the subject, their rights and duties are the same. Few of the States have any such legislation, however, and Louisiana is perhaps the only one which has a judicial decision on the subject. In a case in that State the court defined a druggist to be "one who sells drugs without compounding or preparing them ; and so is a more limited term than apothecary."

The Code Napoleon recognizes and enforces this distinction. The apothecaries are assumed to be men of regular pharmaceutical education, and can compound and dispense medicines. The druggists, however, are classed with the grocers, and can sell only at wholesale or in large quantities.

This distinction is recognized also in Italy, and in a case under the modern Roman Code, four druggists were charged with *pulverizing* and selling chinchona bark, and it was held that this simple operation could only be performed by apothecaries.

In England, at the beginning of the sixteenth century, there were only two recognized classes of medical practitioners. These were the physicians and the surgeons. The physicians were formed into a corporation in 1518, and the surgeons and barbers into another in 1540. This left a large number of irregular practitioners not coming strictly under either of these heads, and, as many of them had shops where they sold medicines, they were styled apothecaries, and were legalized by a Parliamentary Act in 1543.

In 1606, James I. formed them, with the grocers, into one of the city companies of London. In 1617, they separated from the grocers, and set up for themselves, under the firm-name of the "Apothecaries of the City of London." In addition to their special function of compounding and dispensing remedies, the apothecaries claimed an ancient right to prescribe medicines. This claim was disputed by the physicians with more or less vigor during the seventeenth century, until the question came before the courts for decision. In 1703, the House of Lords, as the final appellate court, decided that the apothecaries had the right they claimed, and from that time there has been no attempt to interfere with an apothecary who prescribed for his patients, if his other qualifications were sufficient. In 1722, power was granted the Apothecaries Company to visit the shops of all apothecaries in the city of London, and destroy such drugs as were found to be unfit for use. In 1748, the Company acquired much greater power by an act authorizing it to appoint ten examiners, without whose license no person could compound and sell medicines in London, and for a distance seven miles around it. In 1815, a Board was appointed, consisting of twelve members of the Apothecaries Society, whose duty it was to examine and license all apothecaries in England and Wales. The Board having the power to require professional knowledge before the issuing of a license, soon began to specify the courses of lectures, or terms of hospital practice necessary to enable a student to be licensed, and from this power granted to it, date really the organization of medical schools. Up to this time there had been no way of enforcing any educational requirement, and as a result there were a large number of illiterate and utterly incompetent physicians practising in Great Britain. The powers of the Board pertained only to medical knowledge, and being unable to go beyond this, it frequently happened that applicants for licenses were exceedingly deficient in preliminary knowledge, and in 1860 an examination in the arts was established for all applicants except those possessing a university degree. The question was raised a short time since whether, under this law, women could be admitted to practise medicine in Great Britain, and the Board issued the license, although declining to decide that the law gave the privilege.

From these statements it will be seen that the status of an apothecary in Great Britain is that of a general practitioner of medicine who supplies his patients with medicines. The Apothecaries Society has never possessed and never attempted to issue licenses merely to deal in drugs, and until 1868 any person could open a shop and deal in drugs and poisons. In that year, however, the Pharmacy Act was passed, and no person can now engage in this business without being registered, and to secure such registration, the applicant must pass an examination in Latin, English, arith-

metic, prescriptions, practical dispensing, pharmacy, materia medica, botany and chemistry. It will be seen, therefore, that apothecaries have different powers in the different countries. On the Continent their functions seem to be to dispense without prescribing, and in this country this is their usual business, though prescriptions are occasionally given by them. Apothecaries, as has been stated, do not differ from druggists except as State legislation may define their powers.

In preparing his prescriptions an apothecary or druggist is held to a strict liability for all mistakes in compounding and also for the good quality of his drugs. In reference to the first point, an examination of the cases decided in the courts, show that few excuses will avail the apothecary who has allowed a harmful drug to be put up in place of an innocent one, and this applies as well to the employees of the apothecary as to himself. It cannot be said, however, that an absolute and unqualified guarantee is exacted, so as to hold the apothecary responsible for every article that goes out of his establishment. It is necessary to show some degree of negligence. This may be very slight and the subject of inference only. If, for instance, there should be a malicious substitution by a third person of a poison in a jar of innocent drugs on the shelf of a drug store, and this substitution was made without the knowledge of the druggist, and if there was nothing to put him on his guard, the substances being similar in color, consistency, smell, etc., the druggist would not probably be held civilly liable for injuries following the sale of the poison. This is the view of the best text writers, though the cases do not directly cover the point.

This would seem to be the inference from the case of Thomas *vs.* Winchester (2 N. Y., 397), one of the leading cases, on a druggist's liability. In that case a physician in Western New York ordered for Mrs. Thomas a dose of extract of dandelion, and what was supposed to be this drug was bought from Dr. Foord, a druggist and physician. The drug was taken from a jar labelled "½ lb. dandelion, prepared by A. Gilbert, No. 108 John St., N. Y." This jar with its contents had been bought from James S. Aspinwall, who bought it from the defendant, Winchester. Gilbert was an employee of Winchester's, and had acquired a reputation in the preparation of drugs, so that the labels with his name were used by Winchester. The jar in reality contained extract of belladonna, a drug similar in appearance to dandelion, and the mistake was not known until it had passed through the several persons mentioned, and was taken by Mrs. Thomas, in the prescription, to her very serious injury. Suit was brought for damages against Winchester, and after a long contest the Court of Appeals decided that he was liable for the mistake made. If the patient had died from the dose of belladonna the dispensing druggist, Foord, would have been liable for manslaughter, notwithstanding his lack of knowledge of the mistake, on the ground that there was a statutory liability imposed for dispensing poison in place of proper medicine. This would also have been true of Gilbert, who was the person who really made the mistake, but as the action was a civil one for damages, Winchester was held to be the responsible person.

In a Kentucky case, Hollenback *vs.* Fleet (13 B. Monroe, 219), the plaintiff called for a mixture of snake-root and Peruvian bark, and upon taking the dose suffered great pain, and found his health permanently injured. It was discovered that the patient had swallowed some cantharides. This drug was not put up with the prescription, but had been ground previously to the snake-root and the mill had not been properly cleaned afterward. The defendant sought to escape liability on the ground that it was an accidental mistake, and asked the Court if he was to be considered an insurer. The Court held in response to this, that there was "no good reason why a vendor of drugs should in his business be entitled to a relaxation of the rule which applies to vendors of provisions, which is, that the vendor undertakes and insures that the article is wholesome."

In another case, Hansford *vs.* Payne (11 Bush., 380), the apothecary sold croton oil in place of linseed oil, and the patient died in consequence of taking the drug. His widow then brought suit against the druggist and recovered heavy damages.

The druggist is not freed from this strict responsibility, because the physician may have made a mistake in writing out the prescription. An exact compliance with the prescription in such a case does not avail as a defence. The druggist is supposed to have sufficient professional knowledge to prevent any harmful results in such cases. If he fills out the order as written, he is jointly liable with the physician for any harm that may result.

In reference to the liability for selling weak or adulterated drugs the druggist is held to a strict account. This liability exists even without statutory enactments, as every vendor of provisions by the common law was held to warrant their good quality, and in this regard apothecaries were held to come under the heading of provision vendors. Almost all the States have, nevertheless, laws making any adulterations of drugs an offence punishable either with fine or imprisonment, or both. Such laws are generally expected to be executed by State or local Boards of Health, and many of the States give such bodies special powers in the matter. Laws of this character are of quite recent development, and it is perhaps too soon to hold Boards of Health responsible for the existence of adulterated drugs in actual and open sale. Sufficient knowledge in most cases has however been secured as to the usual forms of adulteration, and, with a sufficient appropriation and competent officers to administer the law, there is becoming less and less reason why infractions of the law should not be speedily detected and punished. In many of the cities this kind of sanitary work is carefully attended to, and in the city of New York Dr. Cyrus Edson has been very vigorous and successful in ferreting out adulterations and in punishing offenders. The importance of such work is becoming every day more manifest, and as the public becomes better informed as to the extent and character of adulterations, the tendency is to increase the powers of Boards of Health.

GENERAL GRANT'S CONDITION.

It is a matter of deep regret that the grave suspicions entertained of the serious nature of General Grant's disease are confirmed by a diagnosis of epithelioma of the

tongue and fauces. This disease, the name of which is now perhaps heard of by the general public for the first time, assumes an importance as to study which it could never otherwise obtain. Consequently the daily papers are educating the people with regard to it so that the terms epithelioma, malignancy, and infiltration will be as well understood as in former times were those of suppuration, pus-track, and bullet-cysts. As might have been anticipated under the circumstances, the published reports of the General's condition are very much exaggerated. The disease is by no means as extensive as is generally believed. In fact, the ulcerations, small in extent, are limited to the right pillars of the fauces, the anterior one being perforated at its base. The adjoining right side of the root of the tongue is indurated to a slight extent, as is also a neighboring gland under the angle of the jaw on the right side of the neck. The roof of the mouth, along the line of the hard palate and to the right of the median line, contains three small warty-like excrescences, which show a tendency toward cell-proliferation. The epiglottis is free from any abnormality, as are all other parts of the throat.

Although the induration of the tongue has existed more or less since last fall, when the patient was first seen by Dr. Douglas, the ulcerations have appeared quite recently. It was during their progress that the General suffered from pain in the right ear, which now has been entirely relieved by the local application of a four per cent. solution of cocaine. Under the same treatment all pain in deglutition is now entirely controlled, and the patient is kept in a very comfortable state. The pulse, which is normally sixty per minute, occasionally reaches eighty beats. The bodily temperature is normal. The appetite is fair, which is saying everything in its favor, as the General is not a hearty eater. His bodily condition is, however, much below par, and is more to be considered at present than the local disease. The treatment of the case has been judiciously conservative from the start. The fluid extract of coca is administered internally, and iodoform is dusted upon the ulcerations. Contrary to the general impression, the tongue itself is not ulcerated, nor has it been, as far as we can learn, at any time during the progress of the disease. The troublesome tooth said to have been extracted for the relief of lingual ulceration was on the opposite or sound side of the mouth, and was removed to relieve a persistent ache of the left ear.

RECENT CONTRIBUTIONS TO THE CHEMISTRY AND THERAPEUTICAL PROPERTIES OF ERGOT.

Great confusion has existed as to the chemical constituents of ergot. The so-called ergotin of Bonjean, Wiggers, Tanret, and others is not probably a fixed compound, but a mixture. The most approved analysis of ergot heretofore has been that of Dragendorff, who stated that ergot contains (1) sclerotinic acid; (2) sclero-mucin; and (3) coloring matters. These are claimed to represent the therapeutical properties of the drug, which has, besides, an oil and a number of alkaloids and other ingredients, all being inert. The ecbolin and ergotina of Winckler are claimed by Dragendorff to be mixtures.

Of the three substances mentioned above, sclerotinic acid has been supposed to represent most perfectly the physiological properties of ergot, and this view is supported even by such careful writers as Nothnagel and Rossbach.

Recently R. Kobert, as the result of numerous experimental researches in the Pharmacological Laboratory at Strassburg, announces (*Archiv f. exp. Path. u. Pharm.*, Bd. xviii.) that the active constituents of ergot are the following three substances: (1) ergotin acid; (2) sphacelin acid; (3) cornutin.

It is well agreed that a watery extract of ergot gathered at the right time contains the active principles of the fungus, and that in physiological doses this extract has the following effects: (1) it powerfully stimulates the vaso-motor centre, thus constricting the blood-vessels; (2) it produces peristaltic and tetanic contractions of the uterus; (3) in toxic doses it produces convulsions (*ergotismus convulsivus*) or gangrene (*ergotismus gangræno-sus*). Other toxic effects, such as paralysis, ataxia, ulcerations of Peyer's patches, and intestinal hemorrhages may also be produced. Returning now to the researches of R. Kobert, we find that he asserts that ergotinacid forms really the chief constituent of sclerotinic acid, that it possesses no tonic power upon the blood-vessels, but causes the other effects upon the heart, respiration, and nervous system attributed to sclerotinic acid. It does not, however, have any effect upon the pregnant or non-pregnant uterus. He also claims that sclerotinic acid has no ecbolic action, and maintains the general physiological identity of these two acids. As to this alleged ecbolic action of sclerotinic acid, authorities very greatly differ. Dragendorff, Nothnagel and Rossbach, Nitikin and Marckwald claim that this acid acts upon the uterus, while Dr. C. M. Seltzer (quoted by Wood) does not find this to be the case, and H. Munk (*Inaug. Diss.*, Tübingen, 1884—*Centralbl. f. klin. Med.*, 1885, No. 5) and Kobert independently observed no effects whatever upon the uterus. From this it is to be inferred at least that the sclerotinic acid is an uncertain preparation.

The second substance isolated by Kobert was called sphacelinacid. It is a non-nitrogenous body, soluble in alcohol. It does not produce convulsions, but does stimulate the vaso-motor centre, and, in toxic amounts, causes gangrene, ulcerations of Peyer's patches, ataxia, and paresis. This substance is believed to be the active agent in producing gangrenous ergotism. The sphacelinacid is believed also, though on not very strong evidence, to produce tetanic, but not peristaltic, contractions of the uterus. The third compound, isolated by Kobert, cornutin, is closely allied, chemically, with ergotinin, but while the latter is inert, the former is strongly poisonous. It produces convulsions in frogs and mammals; it powerfully stimulates the vaso-motor centre without directly affecting the heart, and consequently causes a rise in blood-pressure. It is more active than sphacelinacid in this respect. It produces irregular peristaltic contractions of the uterus, but never tetanus uteri. It is the agent in causing convulsive ergotism.

Kobert criticises a recent contribution of M. Marckwald (*Du Bois Reymond's Archiv*, 1884, p. 434) to this same subject. Marckwald experimented with various kinds of ergot preparations. Since the ordinary watery extracts are irregular mixtures of inorganic salts, ergotinacid, and cornutin, our critic thinks it not surprising

that they sometimes caused a rise, sometimes a fall of blood-pressure. Those preparations which have a good deal of ergotinacid lower blood-pressure, those containing cornutin raise it.

Tanret's ergotinin was found to have no action on the uterus. In this Marckwald is confirmed by Tarnier, who has abolished it from the Maternité Hospital. Wernich's ergotin and Witte's sclerotinic acid were found to have a powerful action on the uterus, but Kobert claims that these preparations do not represent special chemical compounds, but are impure mixtures. Neither dialysed ergotinum nor ergotinin had any action upon the blood-vessels, while sclerotinic acid was found to be a powerful hæmostatic.

The conclusion to be drawn from the foregoing review is that, until chemists and pharmacologists are more agreed upon the composition of ergot, it is better for the practitioner to trust to watery extracts.

Some additional contributions to the therapeutics and toxicology of ergot have recently been made.

Scheffer (*Gaz. Méd. de Strasbourg*, 1884, No. 11, p. 199) relates the history of a case of acute ergotism.

Rulle ("Ueber Mutterkorn," *St. Petersb. Med. Woch.*, 1884, No. 18) makes a plea for the use of ergot after delivery as a preventive of puerperal fever. He thinks that by keeping the uterus firmly contracted septic poison is less likely to enter the system. This view has been supported by Carblom and Worms, and by Thomas and others in this country.

Bourneville and Bricon (*Prog. Méd.*, 1884, No. 18) reach the somewhat empty conclusion that sclerotinic acid is of no especial value in epilepsy.

A. Angelini (*Gazz. degli Osp.*, 1884, T. v., p. 42) makes a plea for the local use of ergot. It has been employed in this country as a gargle in the treatment of pharyngitis, but ergot never has obtained a reputation as a topical application, and from *à priori* reasons we should say it never could.

Deboué (Paris: G. Masson, 1883; *Centralbl. f. Klin. Med.*, 1885, No. 5) discusses the value of ergot in typhoid fever. Since, according to Kobert, one of the constituents of ergot, sphacelinacid, produces the very lesions of this fever, it is only homœopaths who would expect anything from the drug.

Schatz (*Deut. Med. Woch.*, 1884, No. 48) finds that the subcutaneous use of ergot (Kohlmann's fluid extract) in parturition is attended with very uncertain results.

HOW TO KEEP INFECTIOUS DISEASES FROM SCHOOLS.

We have lately received a small pamphlet entitled a "Code of Rules for the Prevention of Infectious and Contagious Diseases in Schools."[1] It consists of a series of resolutions passed by the Medical Officers of School Associations, and embodies the results of careful study and extensive experience. The resulting "Code" contains much that will be of value, therefore, to teachers and medical men.

One of the first points insisted upon is that of undivided medical responsibility. Each school should have a medical officer, and only one. Among other suggestions are these: In large schools it is advised that when practicable there be two establishments, one for children under eleven, and another for pupils above that age. The water and milk supply should be carefully inspected.

There is yet considerable diversity of opinion as to what measures are best and most practicable for keeping the infectious eruptive fevers from schools. The problem differs necessarily in accordance with the location of the school, whether in city or town, and its character, whether public or private. It has been the experience of physicians that measles, scarlet-fever, diphtheria, pertussis will appear among school-children despite the greatest precautions. And the public is not yet educated up to the point when it will co-operate heartily and intelligently with health officers, or second them in still more stringent efforts at prevention. We must, therefore, continue making slow improvements, and learning by experience what are the best modes to check infection without using methods too intricate and burdensome.

A step in this direction was made recently in the attempt to instruct teachers in the early symptoms of the eruptive fevers and other contagious maladies.

According to the "Code" before us, which is intended chiefly for private institutions, every large school should have a detached infirmary, and where possible a separate building for infectious diseases. In small schools there should be a "sick-room" at the top of the house. The "Code" lays down an elaborate set of rules regarding the issuing of medical certificates to pupils, so as to insure against the bringing of any disease into the school upon admission or after vacation or holidays. Quarantine rules are also given.

The following quarantine times after *exposure* to infection are considered safe, provided thorough disinfection be carried out on the pupil's return to school: Diphtheria, twelve days' quarantine; scarlet fever, fourteen; measles, sixteen; German measles (Rötheln, or epidemic roseola), sixteen; chicken-pox, eighteen; small-pox, eighteen; mumps, twenty-four; whooping-cough, twenty-one.

With regard to that most important question, "When may a pupil who has had an infectious disease go home, or rejoin the school?" the following rules are endorsed, provided patient and clothes are *thoroughly* disinfected: "A pupil may go home, or rejoin the school, after scarlet fever, in not less than six weeks from the date of the rash, *if* desquamation have completely ceased, and there be no appearance of sore throat; measles, in not less than three weeks from the date of the rash, *if* all desquamation and cough have ceased; German measles (Rötheln, or epidemic roseola), in two or three weeks, the exact time depending upon the nature of the attack; small-pox and chicken-pox, when every scab has fallen off; mumps, in four weeks from the commencement, *if* all swelling has subsided; whooping-cough, after six weeks from the commencement of the whooping, provided the characteristic spasmodic cough and the whooping have ceased, or earlier, *if* all cough has completely passed away; diphtheria, in not less than three weeks, when convalescence is completed, there being no longer any form of sore throat, or any kind of discharge from the throat, nose, eyes, ears, etc., and no albuminuria."

[1] London: J. & A. Churchill.

The "Code" strongly advises against the breaking up and dispersing a school when an epidemic has appeared. The responsibility for withdrawing the pupils should lie with the parents, not the teachers.

WHY THE MEDICAL RECORD TOOK SUCH A FAVORABLE VIEW OF GENERAL GRANT'S CASE.

In view of the recent developments in General Grant's condition, the RECORD's bulletin of two weeks ago, which has been so largely quoted by the press of the country, requires some explanation. It is fair to state that the facts at that time presented by THE MEDICAL RECORD were founded on the best of authority, that of Dr. Fordyce Barker, the attending physician of General Grant, and this explanation is manifest in the following note:

24 EAST THIRTY-EIGHTH STREET.

DEAR DOCTOR SHRADY:

The statement which I made to you was literally true at the time that I made it, and I am certain that Dr. Douglas would then have made precisely the same. I saw Dr. Douglas last evening, and he then said, that what I had told you was exactly what he should have said at the time. But the Monday after I saw you, the action of Congress had a most depressing effect on General Grant, his vital powers suddenly broke down, and the local malady speedily assumed a new aspect. The newspaper accounts have been greatly exaggerated, and we have never anticipated any such a speedy termination as they have indicated.

I do not believe that Dr. Douglas ever used the word cancer in connection with the case. We have always spoken of it as epithelioma, of a malignant type probably. It was greatly improved for a time by the local treatment of Dr. Douglas, and the local condition was manifestly improving until the moral shock broke down his general system. Ever faithfully,

FORDYCE BARKER.

WEDNESDAY NOON, March 4, 1885.

"KOLLERISM" AND "KOLLERIZATION."—"Observations of Fifty Operations on the Eye under Kollerism," was the title of an essay read before the Montgomery (Ala.) County Medical and Surgical Society, on February 21st, by Dr. B. J. Baldwin. In the course of his remarks Dr. Baldwin said, "I propose in this article to introduce the words 'Kollerization,' 'Kollerism,' and 'Kollerized.' I have not heard of their being used before, and the thought has occurred to me that they would be convenient terms to employ. If the profession will adopt these words, it will not only facilitate the expression of an idea, but their use will be a merited tribute to the fame of Dr. Koller." Out of the fifty cases operated on under cocaine anæsthesia, Dr. Baldwin only had three failures, and these three failures were in eyes whose conjunctiva and cornea were very much diseased, or covered with cicatrices. He regarded the failure in such cases as due to the bad absorptive powers of the epithelium. In nine cases of the fifty there was no dilatation of the pupil. He had one case of cocaine poisoning, the serious effects of which passed over in eight minutes. He regarded cocaine as "divinely successful."

News of the Week.

BEQUEST TO A HOSPITAL.—Mrs. Mary Fletcher, of Burlington, Vt., who died recently, left $200,000—nearly the whole of her estate—to the hospital which she founded and which goes by her name.

SUICIDE OF A MEDICAL STUDENT.—The report reaches us that a young medical student, in a St. Louis, Mo., medical college, shot himself on March 2d because he had failed to pass his examinations.

LUCILLE DUDLEY.—English medical journals unite in saying, on the strength of her past history, that Mrs. Dudley is insane.

A CREMATION SOCIETY has been organized in Buffalo, with a capital of $10,000.
